Table 50-2 offers a listing of key MH services and the professionals who provide them. A PCC whose community does not offer the full array of key services will need to partner with others, including developmental-behavioral pediatricians, local school systems, early childhood educators, parent educators, MH providers, and advocates, to address gaps. Given the necessity for child psychiatry consultation and shortage of child psychiatrists, many regions in the United States are piloting new models of psychiatry consultation by video and telephone. One of the earliest of these, the Massachusetts Child Psychiatry Access Project (MCPAP), has demonstrated an increase in participating PCCs' comfort in managing common childhood disorders and improvement in the outcomes of children in their care.

### Tracking Referrals

Because stigma and administrative, financial, and logistical barriers often prevent children from seeking or receiving MH specialty care, it is important that PCCs track the children they refer. If the family is unsuccessful in acquiring timely assessment or treatment for the child, the PCC can offer generic interventions as described earlier, further primary care assessment and management strategies, or periodic telephone contacts to monitor for worsening or emergent problems. Unfortunately, it may be necessary in some instances to use emergency procedures to obtain needed services.

### Communication

The decision to involve a specialist does not end the PCC's role in the care of the child. It does mean that the PCC's role will include communicating with the specialist. As with any other specialty referral, the process is enhanced by conveying to the specialist the nature of the concern and the PCC's specific

questions, results of previous assessment and intervention efforts, and openness to discussion with the professional. Although the Health Insurance Portability and Accountability Act (HIPAA) allows exchange of information among professionals who are involved in the care of a mutual patient, many MH professionals are reluctant to share information without express consent of the child and family. By obtaining written consent and sending it to the MH professional, the PCC can convey interest and facilitate communication.

For children in the foster care system, the assigned social service agency must authorize exchange of information. It is important to collect information from case workers and to convey information back to the worker. If the child changes placement and the caregivers are unaware of previous health assessment, plan of care, and sources of care, the child suffers discontinuity of health care as well as placement. In some situations, the PCC may need to be the primary advocate for the MH of a child in the foster system, expressing concerns and recommendations clearly and repeatedly to the appropriate social service agency.

Forms for exchange of information may facilitate the comanagement process (see *Tools for Practice* at the end of this chapter). Telephone and e-mail contacts may be helpful in some instances.

### Development of a Family-Centered Care Plan

The purpose of a family-centered care plan is to seek improvement in the child's overall emotional health and functioning. It articulates the child's and the family's goals; child and family strengths; service and educational needs; roles of involved service providers, family members, and other caregivers; schedule of follow-up and routine health supervision visits; steps to take in an emergency, if one should occur; and, ultimately, the route to self-care or family care, transition to adult primary care and specialty health services, and the other services and care coordination needed to support the young person's achievement of his educational, social, and vocational goals in adulthood.

A care planning conference is a very helpful (some would say, essential) mechanism to develop and coordinate a plan of care for a child with an MH or SA disorder. Ideally the family, other caregivers, school personnel, case workers, and service providers all participate in the plan's development. If the child has a comorbid medical condition that involves medical specialty care, inclusion of medical specialists is also important. For children in the foster care system, it is essential to include the case worker.

The family should not be placed in the position of transmitting information between professionals who are involved in their child's care; if the inclusion of involved specialists in the care planning conference is not feasible, the PCC needs information from them in advance of the conference to ensure understanding of the child's problems and the options available for further care. Together, the family, PCCs, and other partners can set the timetable of care, determine need for involvement of additional or alternative specialists, and select interventions. They can also establish a plan

**Table 50-2****Sources of Specialty Services for Children With Mental Health Problems and Their Families**

<b>SPECIALTY SERVICES</b>	<b>SOURCES</b>
Psychiatric emergency services	<ul style="list-style-type: none"> <li>• Local mental health screening, triage, and referral service or other intake point for public specialty system</li> <li>• Mobile crisis unit, if available</li> <li>• Child psychiatrist</li> <li>• General psychiatrist with pediatric expertise (or consultation with child psychiatrist)</li> <li>• Emergency department</li> </ul>
Medication consultation or management of patients with problems of high severity (MD or DO required)	<ul style="list-style-type: none"> <li>• Child psychiatrist</li> <li>• General psychiatrist with child expertise or child psychiatry consultation</li> <li>• Neurodevelopmental/developmental-behavioral pediatrician (NDP/DBP)</li> <li>• Adolescent medicine specialist</li> <li>• Pediatric neurologist</li> </ul>
Early Intervention (EI) services	<ul style="list-style-type: none"> <li>• Local public mental health agency</li> <li>• Developmental evaluation agency</li> <li>• NDP/DBP</li> <li>• Child psychiatrist with expertise in young children</li> <li>• EI specialist</li> </ul>
Child protective services	<ul style="list-style-type: none"> <li>• Department of Social Services</li> </ul>

Parenting education	<ul style="list-style-type: none"> <li>• Parent educator trained in evaluated curriculum</li> <li>• Family services agency</li> <li>• LMHP</li> <li>• School system's social work services (some have parenting education programs)</li> <li>• Agricultural extension service (some have parenting education programs)</li> </ul>
Care coordination/case management	<ul style="list-style-type: none"> <li>• LMHP with expertise</li> <li>• Local public mental health agency</li> <li>• Peer support program</li> </ul>
Peer support	<ul style="list-style-type: none"> <li>• Local organization of National Alliance on Mental Illness, National Federation of Families for Children's Mental Health, Family Support Network, Children and Adults With Attention-Deficit/Hyperactivity Disorder</li> <li>• Local public mental health agency</li> <li>• Al-Anon</li> </ul>

From Appendix S1: sources of specialty services for children with mental health problems and their families. *Pediatrics*. 2010;125 (Suppl 3):S126–S127.

for monitoring treatment response and safety and create a common understanding of limits of confidentiality. For adolescents, direct input to the plan is critical for engagement and success of treatment; and their transition to adulthood and to adult care deserves specific attention in the plan. (See Chapter 66, Transitions to Adulthood.)

For children previously involved in MH specialty care, a care plan may already be in place and may omit primary care issues, such as healthy lifestyle (eg, nutrition, exercise, sleep, stress management, social support), routine health supervision, or care of chronic medical conditions. In this instance, rather than developing a new or alternative plan of care, the PCC can augment the existing plan by pointing to the roles that she can play in coordinating and complementing the care of the MH specialists.

Some children with severely impairing emotional disturbance may have an MH or EI care manager involved in their care; if so, the participation of this care manager is central to the process. The care manager may organize periodic meetings of teachers, social workers, and agency representatives involved with the child and family. In the MH specialty system, such processes are sometimes called a system-of-care approach—a coordination system built around the family's strengths and priorities. If such a system exists, the PCC (or his staff representative), often inadvertently omitted, can join in that process as an alternative to convening a primary care conference.

Participation in care planning is time consuming. A primary care-integrated MH specialist can be a tremendous asset to the PCC in the care planning process, representing primary care perspectives and ensuring coordination of medical and MH specialty care. In the absence of an integrated MH specialist, participation by the PCC or other members of the primary care team is valuable to the child and family and may ultimately produce efficiencies in the care of children and adolescents with complex conditions. In the future, secure electronic methods may be developed to house care plans that are accessible to the family and to all those participating in the child's care.

See the Tools for Practice section of this chapter for sample care plans.

## MONITORING CHILDREN WITH MENTAL HEALTH AND SUBSTANCE ABUSE PROBLEMS

Office systems used to organize and monitor the care of children with chronic medical conditions such as asthma and diabetes can be applied to the care of children with MH and SA conditions. Elements particularly important for the care of children with MH and SA problems include the following:

- *Registries* (lists of children with MH problems that require monitoring): Registries can be developed within the practice for children and youth with positive psychosocial screens, children with concerns that do not rise to the level of a diagnosis, those who are not yet ready to seek or accept care for MH problems, those with social concerns that pose a risk to the child (eg, infants whose

mothers have a positive screen for postpartum depression, children exposed to trauma), children with disorders, and children prescribed psychotropic medication.

- *Assignment of staff roles* in care of children on the MH/SA registry. Examples might include the following:
  - Obtaining parental permission for information exchange with the MH or SA professional and school or child care
  - Tracking referral completion
  - Scheduling return to the PCC's office
  - Gathering collateral data (eg, school or child care progress reports, functional assessment scale)
  - Reaching out to child and family between visits
  - Monitoring medication effects and side effects
- *Forms and tools* to facilitate these office processes
- *Educational tools and resources* for youth and families (see Box 50-2)
- *Directory of community resources*, including providers of evidence-based psychosocial treatments and parenting programs (see Table 50-2 for a listing of key services)
- *Resources to support PCCs* in decision making
- *Coding and billing strategies* to optimize payment

The interval between primary care contacts will be determined by the acuity and severity of the child's condition; the child's and family's strengths, needs, and preferences; adverse effects and monitoring requirements of any treatments; the role of other professionals in monitoring the child; and the level of the child's impairment. Just as spirometry measures pulmonary function and assists the PCC in monitoring children with asthma, global functional assessment scales assist the PCC in monitoring children with mental illness.

When children are being followed by specialists, the PCC and specialists will need a coordinated follow-up plan, developed with the family. To assess the child's current status, they may rely on progress

- Healthy Children ([www.healthychildren.org](http://www.healthychildren.org))
- Zero to Three ([www.zerotothree.org](http://www.zerotothree.org))
- National Alliance on Mental Illness ([www.nami.org](http://www.nami.org))
- American Psychological Association ([www.apa.org](http://www.apa.org))
- Children and Adults With Attention-Deficit/Hyperactivity Disorder ([www.chadd.org](http://www.chadd.org))
- National Federation of Families for Children's Mental Health ([www.ffcmh.org](http://www.ffcmh.org))
- Substance Abuse and Mental Health Services Administration ([www.samhsa.gov](http://www.samhsa.gov))
- American Academy of Child & Adolescent Psychiatry ([www.aacap.org](http://www.aacap.org))
- The Compassionate Friends ([www.compassionatefriends.org](http://www.compassionatefriends.org))

reports from other professionals involved in the child's care; functional assessment scales completed by the parent, teacher, and youth; and their own clinical assessment. When pharmacologic agents are part of the treatment plan, laboratory tests may be necessary to monitor levels and adverse effects. Responsibility for each of these roles should be clearly assigned. Responsibility for routine health supervision and monitoring of the child's comorbid medical conditions falls to the PCC.

Applying chronic care principles to the child's care does not mean that the child's condition is permanent. Children and families can and do recover from mental illnesses. The PCC can periodically reconvene a conference with the family (and youth) to determine whether further assessment or a change of plan is indicated.

## CODING AND BILLING FOR MENTAL HEALTH SERVICES IN PRIMARY CARE

Many PCCs are reluctant to elicit and address MH concerns because of inadequate payment for the additional time required. The coding guidance that follows may assist in overcoming this barrier.

### Evaluation and Management (E and M) Codes

The following *Current Procedural Terminology (CPT)* codes may be used for primary care visits involving MH services:

- Office or other outpatient services (new patient): **99201–99205**
- Office or other outpatient services (established patient): **99211–99215**
- Office or other outpatient consultations (new or established patient): **99241–99245**
- Preventive medicine services (new patient): **99381–99385**
- Preventive medicine services (established patient): **99391–99395**
- Brief emotional behavioral assessment (new or established patient): **96127**

### The Primary Care Clinician as Mental Health Consultant

Under specific circumstances, a PCC may serve as a consultant in addressing children's MH concerns (as well as other concerns). Because consultation codes have higher relative value units (RVUs) than office or other outpatient service codes, they are usually paid at a higher rate. The following criteria, known as the 3 Rs, must be met for a service to qualify as a consultation:

- A *request* for consultation must be made by an appropriate source (not a patient or family member) and documented in the chart.
- The consulting PCC must *render* an opinion or advice back to the requesting source.
- The consulting PCC must provide a written *report* back to the requesting source.

If these criteria are met, a PCC can report consultation codes **99241–99245** for services provided. The request for consultation may come from any appropriate source, such as school personnel, another colleague in the same practice, a therapist, a nurse

practitioner, or an attorney. The PCC cannot use consultation codes for return visits related to the initial consultation.

The consulting PCC can be a physician or nonphysician practitioner (NPP) with expertise in the relevant clinical area. If an NPP is performing the MH consultation, code **90791** (psychiatric diagnostic evaluation) could be more appropriate for describing the service.

### The “Greater Than 50 Percent” Rule

Frequently, MH visits require considerable time spent in counseling or care coordination. When these aspects take up more than 50% of the face-to-face time spent with a patient, the PCC can use time as the key or controlling factor for a particular evaluation and management service rather than the history, physical examination, or medical decision-making elements that would otherwise be necessary to support that code. To code these encounters, the PCC must carefully document the total time spent with the patient and the amount of that time spent in counseling or care coordination. Suppose, for example, the physician spends 25 minutes face-to-face with an established patient and 15 of those minutes are spent in counseling or care coordination. The typical duration of code **99214** is 25 minutes. Because more than 50% of that time was spent in counseling or care coordination, the PCC could use **99214** regardless of the history, physical examination, or medical decision making provided during that encounter.

### Prolonged Services

If the PCC spends at least 30 minutes longer, face-to-face, than the time typical for a particular visit, the PCC may additionally report prolonged service codes **99354–99355**. Time must be spent on the same day as the visit, but does not need to be continuous. The prolonged service codes are add-on codes, meaning they are reported separately in addition to the appropriate code for the service provided (eg, office or other outpatient service codes). It is essential to document the time and services provided to substantiate the use of these prolonged service codes.

Even correct coding and documentation in the medical record may not result in payment for prolonged services because of a payer's policy not to cover them. If the patient is on a capitated plan, the PCC may request authorization to bill the family directly for these noncovered services.

Few payers pay PCCs for non-face-to-face prolonged services codes **99358–99359**, care plan oversight codes **99339–99340**, and telephone care codes **99441–99443**.

## SUMMARY

Increasingly, pediatric PCCs are expected to be a source of MH care, a gateway to specialty MH care, and a source of primary care that is coordinated with specialty MH care. With the requisite competencies and with office systems in place to organize and monitor the care of children with MH problems, PCCs are positioned to fulfill these roles. They can recognize those emergent situations that compel an immediate intervention; find ways to support and help the family

that is resistant to seeking psychosocial care; assess and manage the child in the primary care setting—in a role similar to that of an MH specialist—or co-manage the child's care with MH professionals. By applying evidence-based methods, the PCC can reduce distress of the child and family and improve the child's functioning across a variety of MH problems, even in the absence of a diagnosis and while awaiting MH specialty assessment and treatment.

Factors determining the role of the PCC in a particular child's care include the type and severity of problem the child is experiencing, the family's preferences, the PCC's comfort, and accessibility of MH specialists with pediatric expertise. The PCC has a critical role to play in facilitating development of a family-centered plan that coordinates the child's care and defines roles for the family members and professionals involved.

## Chapter 51

# CARE OF CHILDREN WITH SPECIAL HEALTH CARE NEEDS

Ruth E. K. Stein, MD; Sonia O. Imaizumi, MD;  
Lynn F. Davidson, MD

All children experience minor illnesses and injuries. Although most children have no ongoing consequences from these episodes, some children have more serious or recurrent impairments or disruptions

of their health with which they live for prolonged periods. These conditions, and the children who have them, have been given many names over the past decades. Some authorities have referred to them as having chronic illness, but some of these children are not ill. Other authors have referred to them as having disabilities or handicaps, but many children do not exhibit these features. The trend recently has been to refer to these children and youth as having special health care needs (CSHCN or CYSHCN). In addition, the subgroup of more severely affected children whose conditions involve more than one body system have been referred to as children with medical complexity. The term *children with special health care needs* was originally introduced as a euphemism for the other terms used earlier to describe these children with ongoing conditions. More recently, the Maternal and Child Health Bureau has used CYSHCN to include children who do not currently have any condition or impairment but who are at risk for one, such as foster children. Because no agreement exists on which children to include in the at-risk category, CYSHCN are referred to in this chapter as children with ongoing or chronic conditions.

## DEFINITION

Identifying children with ongoing or chronic conditions requires a definition. In fact, many current definitions are quite similar. One useful definition has 3 key components: the presence of a condition, a duration or expected duration of at least 1 year, and a consequence for the child. This definition recognizes 3 main types of consequences: having a functional limitation (something that prevents the child from participating in the normal range of age-appropriate activities), increased use of health care services beyond those used by age mates, and reliance on compensatory mechanisms (medication, special treatments, assistive devices, or personal assistance) to function.

The definition adopted by the Maternal and Child Health Bureau combines the latter 2 categories of consequences and considers *at-risk* children as well: “Those children who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally.” Because no validated method currently exists for fully operationalizing the Maternal and Child Health Bureau definition that includes those at risk, and because the concept of compensatory mechanisms is conceptually and critically distinct from receipt of services, the definition with 3 key components is used here. Compensatory mechanisms are especially important as medical care finds new ways to minimize functional limitations and allows children to carry on with their normal activities. For example, a child with a pacemaker or one who is on insulin, inhaled steroids, or overnight infusions may only be able to *pass* and function as a healthy child because of those treatments and may have few, if any, other consequences of his underlying condition. Unless these special aspects of care are

considered, children whose compensatory mechanisms are successful may be counted as healthy children, and thus the success of treatments and the need to sustain them will be underappreciated, undercounted, and underfunded.

The use of an umbrella definition that includes children regardless of their diagnosis is important because the epidemiology of ongoing conditions in children and adolescents includes a few common conditions, such as asthma, developmental delay, or diabetes, and far more uncommon conditions, such as congenital malformations and inborn errors of metabolism, malignancies, and a wide range of acquired injuries and illnesses. Even though the names of many of these conditions are known, an all-inclusive list would be extremely long, and many children would still not find their diagnoses on the list. Because of this circumstance, thinking of CYSHCN as sharing some common characteristics of duration and consequences without necessarily naming the condition is far more convenient for many purposes other than biomedical treatment. However, the specific diagnosis is extremely important when providing the appropriate specific treatments for the condition. Many specific conditions and their treatment are described elsewhere in this text.

## PREVALENCE

Estimates suggest that between 15% and 20% of children have some impairment or underlying condition that qualifies them as CYSHCN, depending on how the definition is applied. Some experience only minor, if any, difficulties from their conditions, but others are severely affected. Between one-half and two-thirds of the children who meet the definition experience a functional limitation, either with or without other types of consequences. Approximately 10% of all children who have ongoing conditions experience consequences in all 3 categories, (functional limitations, increased use of services, and need for compensatory mechanisms) and these are often the children with the most severe conditions.

Three factors will likely lead to an increase in the numbers of children with ongoing conditions. The first factor is improvements in early detection and diagnosis as a result of molecular genetics. Second is the use of preventive interventions that postpone the onset of the full manifestations of some conditions to which children are genetically vulnerable, thus increasing the number of children receiving care. Finally, medical advances increase the numbers of children who survive their conditions, sometimes with prolonged dependence on technology.

## EFFECT OF THE CONDITIONS

Ongoing conditions vary in their severity from very mild, requiring little health care, to extremely debilitating affecting every aspect of life and requiring intensive health care services. However, all ongoing conditions have some implications for children’s long-range health and service needs and in many cases for their longevity as well. Additionally, all conditions

affect how families view their children and their vulnerability. Research has demonstrated that there is not always a correlation between the pediatrician's sense of the severity of the condition and the family's perception of its effect or influence on their child and their lives.

Children with functional limitations tend to experience fewer of the usual activities and opportunities for socialization that are important for normal development. Depending on the age of the child and the level of functional limitations, these effects vary considerably. Motor or sensory impairments may limit exploratory opportunities to varying degrees and therefore can influence the child's developmental trajectory. Even children who do not have limitations are sometimes overprotected by their parents, which can result in unnecessary restrictions of opportunity for developing important social skills and psychological well-being. This is referred to as *the vulnerable child syndrome*.

Parents face a great deal of physical, emotional, and financial strain, and in many cases the entire family experiences significant social isolation. All of these stresses place additional burdens and demands on family members. Some studies suggest that parents who assume major caregiving responsibilities for children with severe conditions are at increased risk for physical and mental health problems and divorce, while others contest these findings.

Siblings and the children themselves are often stigmatized when conditions are visible. In addition, many siblings are forced to function more independently than usual because parental attention may be focused on the child with a condition. They may feel jealous, abandoned, and sad, or they may assume increased adult responsibilities. Sometimes these children become caregivers for the sibling with an ongoing condition or take on the care of younger, healthy siblings.

Conditions that are not obvious can also be particularly challenging emotionally, because children and families face issues regarding if and when to disclose the condition and must navigate between the world of the well and the world of their conditions. The lack of visibility creates uncertainty, and any type of uncertainty is particularly challenging. Most people seem to have the greatest difficulty with conditions that fluctuate in their severity, even when most of the time the children are relatively well. The emotional toll of these conditions is sometimes worse than when there is a stable level of greater dysfunction.

Transition times are especially stressful. Transition times include stages and events such as becoming ambulatory, entering school or child care, moving from one school or community to another, or moving into latency, adolescence, or adulthood. When healthy age-mates move from one major stage to another, the family of a child with an ongoing condition is often confronted with the ways in which their own child is different or with the need to make special accommodations to ensure that medical safety or special needs are managed. Primary care professionals can anticipate that these are times when families may need extra help and support.

## SPECIAL CARE CONSIDERATIONS

The primary care physician (PCP) needs to be aware of multiple special aspects of care of a child with an ongoing health condition and how usual practices may need to be modified. These aspects of care include the provision of health care maintenance and management of acute illness.

### Health Care Supervision

Because many children with ongoing conditions have more contact with the health care system than other children, their parents often assume that they are receiving a full package of services, but often this assumption is not true. The actual number of visits that focus on issues of health care supervision for children with ongoing conditions is much lower than for the general population. Many subspecialists assume that these services are being provided elsewhere. However, studies show that many children with ongoing conditions do not receive the routine screenings that are a part of recommended health care supervision for all children. Many are underimmunized as well. In most cases, this situation represents a failure of care rather than a reflection of recommendations for modification of the immunization schedule because of the child's condition or its treatment. Physicians should be aware of special recommendations concerning live vaccines, especially for immunocompromised patients, and document when vaccines are being modified for that reason. If vaccination is postponed, then the PCP should have a mechanism for remembering to provide appropriate alternate protection or later immunization if possible.

The usual anticipatory guidance should also be provided, although in the case of children with developmental impairments, the guidance should be adjusted to the appropriate developmental stage. This process may be complex, because children with ongoing conditions may develop normally or even be precocious in some areas while lagging in others.

In addition to following the usual health care supervision schedule for age-appropriate screening, specific recommendations exist for many children with ongoing conditions to have additional screening for specific vulnerabilities caused by their primary diseases or by the medications that they take. When sharing responsibility for the care of such patients with subspecialists, the PCP must establish who is providing the routine screening, immunizations, and anticipatory guidance, and who is monitoring these special risks to prevent failures or duplications of care. If a division of services exists, then the family must know this and the reasons that they need to make regular visits to both providers.

### Management of Acute Illness or Injury

Children with ongoing conditions experience the same minor illnesses that affect others in the community. However, every evaluation of a seemingly minor chief complaint requires the treating physician to consider whether the symptoms are complications of the underlying disease process, side effects related to medication taken to treat the condition, or a normal intercurrent event. Even when the child has a

minor illness or injury, physicians also should consider whether the condition or its treatment requires the child to receive any special care or medication adjustment. For example, a child with diabetes who experiences an episode of gastroenteritis is likely to need adjustment to the insulin regimen. A child who is being weaned from steroids or who is on permanent physiologic levels of exogenous steroid may need extra coverage during the illness. A child with vomiting caused by gastroenteritis might require an alternate mode of administration of an essential medication or special monitoring or titration of the dose.

In evaluating the patient and the management plan for the acute minor illness, the physician must check with the parents and older child about whether they have any special concerns or questions. This responsibility is most essential in an encounter in which the treating physician does not know the family, given that the family is often able to distinguish between the child's current and baseline condition in ways that may not be immediately obvious to someone who does not know the patient well. In many instances, the patient or parents will raise practical issues in daily management that may not have occurred to the physician. This circumstance is particularly true when they have experienced similar circumstances in the past. Box 51-1 lists some of the questions to consider in the management of acute illness or injury.

Technology-dependent children comprise a unique group among children and youth with special health care needs. These are children who require both a medical device to compensate for the loss of a vital bodily function and substantial, ongoing care to avoid further disability or death. It is estimated that between 0.1% to 0.25% of children in the United States are technology dependent. Common technologies include: enteral feeding tubes (nasogastric/gastrostomy), medium- to longterm central venous access (for parenteral nutrition, intravenous antibiotics, clotting factor, dialysis), clean intermittent catheterization, ventriculoperitoneal (VP) shunts and respiratory therapies (oxygen, cardiorespiratory [apnea] monitoring, pulse oximetry, tracheostomy care, respiratory support [home mechanical ventilation or positive airway pressure equipment, etc], and nasal cannulae).

## MANAGEMENT OF THE CHILD WITH SPECIAL HEALTH CARE NEEDS

Each health condition requires special biomedical treatment and monitoring to prevent secondary complications and to ensure optimal health and functioning. Regardless of the specific type of condition, there are many aspects of management, goals of treatment, and family challenges that are similar across the full range of physical, developmental, and behavioral conditions. Ideally, the child will receive family-centered care that is accessible, compassionate, comprehensive, continuous, and coordinated at the medical home. Such care should involve all the necessary team members. (See Chapter 6, Medical Home Collaborative Care.)

### BOX 51-1 Assessing Acute Conditions in Children With Ongoing Health Conditions

- Can the chief complaint and associated symptoms be explained by the child's underlying condition?
- Can the chief complaint and associated symptoms be explained by the current or recent medications or other treatments?
- Might the chief complaint and associated symptoms represent a complication of the child's underlying condition or a special vulnerability caused by the underlying condition?
- If so, what special evaluations should be performed?
- How do the child's current physical and laboratory findings differ from the child's baseline?
- Has the child skipped, vomited, or failed to absorb recent medications, and might this circumstance be causing a problem?
- What features of the child's condition are of most concern to the family or patient?
- What do they think the problem is?
- Can these features be explained by the presumptive diagnosis of the acute condition?
- What events or circumstances worry the family or patient most? Is this worry a realistic concern, and can something be done to reassure the family?
- In light of the acute diagnosis, does the child need a modification of usual care or medication? Can this modification be handled at home? If the situation can be handled at home, then what is the plan for follow-up, and should it be modified in light of the child's underlying condition?

## Diagnosis

The detection and confirmation of a condition herald the first stage of management. The care of children with ongoing conditions differs from the care of those with acute conditions in the degree to which the family must be involved actively in care decisions. This is because there are likely to be more care options, decisions to make, and adherence over long periods of time. Moreover, many need longterm treatments that require the physician and the parents to figure out how they can best be implemented in the home. Making choices that fit best into the family's routines and preferences has been shown to enhance adherence. The treatment plan may be developed by the PCP and, where appropriate, the subspecialists in partnership with the family. The clinical care responsibilities may be shared with a subspecialist or the staff of a referral hospital, but the PCP must work out a pattern of communication in which the various responsibilities of each of the parties are delineated. The PCP needs to determine regular mechanisms for communication, ascertain key issues that need to be monitored, and determine how these responsibilities are to be divided amongst all providers. In the case of children with

very rare conditions, especially when the primary expertise is far from the patient's home, the PCP should make sure that the delegated responsibilities are clearly understood and that the expert has reviewed the special issues to monitor and the indications for further consultation in order to ensure the best possible care.

Confirming a diagnosis and discussing its implications with parents and the child are ongoing processes that are never accomplished in a single conference. Parents should be encouraged to ask questions regularly, because they are usually unable to absorb a great deal of information at the time of confirmation of the diagnosis. The PCP should suggest that parents write down their questions and other people's questions and advice and discuss them at each subsequent visit. Providing this mechanism and a socially acceptable way to ask naive or awkward questions can enable family members to address issues they may find embarrassing or difficult. In cases in which the condition is life threatening, it may be appropriate to involve a palliative care specialist to talk about quality of life issues early in the care of the child and family.

Some physicians are uncomfortable sharing uncertainty about answers to questions posed by family members. In most instances the key questions that the parents want answered are related to what will happen to their child. Even the most expert physicians cannot answer such questions except in a probabilistic way. Parents repeatedly state that a cornerstone to working well with pediatricians over time is honesty, including sharing uncertainty or seeking additional information when the physician does not have ready answers.

When the information provided is especially distressing, many parents want to seek a second opinion (see Chapter 49, *Discussing Serious Symptoms, Results, and Diagnoses With the Patient and Family*). In these situations, the PCP should recommend places where this can be accomplished responsibly and offer to make study results available. For some families, the offer of opening the results to scrutiny is reassuring. For others who wish to follow through on the offer, it avoids the need for repeated tests and the awkwardness of their worrying about raising the issue with the physician or finding a way to discuss and reconcile conflicting recommendations.

Grief is a normal reaction to the confirmation of a diagnosis and to the loss of the idealized perfect child. Parents normally go through a series of reactions at the time of diagnosis. These reactions may include shock, denial, anger, sadness, and anxiety. Dealing with denial and anger can be challenging even for a pediatrician skilled in caring for children with complex or serious conditions, especially when the anger is directed at the pediatrician. Care must be taken to recognize the displaced anger and to avoid letting it negatively affect the physician-patient relationship. All parents feel guilty about real or imagined things that might have prevented the condition or led to its earlier recognition. Addressing this guilt as universal is important. When parents are encouraged to share their worries, they often can be reassured that the thing that is the source of their guilty feelings is often unrelated to the child's ongoing condition.

Eventually, reorganization (a normalization of emotional well-being) occurs, but any condition-related event or exacerbation may lead to a resurfacing of a cascade of emotional reactions. Parents may go through these reactions at different rates, and this circumstance can affect their communication with and relationship with the physician. The physician should avoid overreacting to parents' behavior and maintain a professional relationship.

### Developing and Promoting Partnerships With Families

Unlike acute conditions, in which life quickly returns to normal, the disruption caused by ongoing conditions continues or ameliorates slowly. In the long term, families bear the brunt of the care responsibilities, and they need to be full partners in care. (See Chapter 9, *Partnering With Families in Hospital and Community Settings*.)

At times, the traditional medical approach becomes a central barrier to the formation of partnerships with families. Two aspects are particularly problematic. The first problem is the paternalistic and hierarchical nature of medicine, which is often associated with entirely prescriptive decision making. Effective management of a chronic condition or impairment requires the physician to understand that the parents are the experts in raising their child and they assume most of the day-to-day care. Within a short time, some parents will know more, especially about rare conditions, than the average pediatrician, and their expertise should be valued and respected. Even at the beginning, the importance of the parents' role with and knowledge about their own child necessitates active involvement and sharing of responsibility that may run counter to the traditional hierarchical paternalism of the health care system. This shared decision-making process leads to better health outcomes for the child.

The second problem with a traditional medical approach is the emphasis on the deficit model, which focuses entirely on what is *wrong* with the patient, rather than seeing the strengths and assets. Physicians are trained to focus on the problem and fix it. For the most part, chronic conditions cannot be cured entirely, and the challenge for both the family and the PCP is to live with this reality and to minimize the disruption in the child's life as much as possible while still maximizing the child's longer-term future health and potential. To accomplish this task, focus must be placed on the whole child, while assets and impairments must be actively recognized and assessed.

When communication and mutual respect are established among the partners, a care plan can be developed that includes the priorities of all parties, is medically and culturally acceptable, and has a far better chance of being implemented and being successful than a plan that does not recognize the parents' role.

### Goals of Care

Regardless of the nature of the child's condition, the primary goal of care is to contain or minimize its effect

and to provide maximal opportunity for the child to function and develop physically, socially, cognitively, and emotionally. This process involves providing optimal biomedical treatment of the condition and helping the family *normalize* the entire family's life experiences as much as possible. To accomplish this, PCPs should place as few restrictions on the child's activities as possible, limiting only these activities that are absolutely necessary to avoid. Additionally, the care plan should be implemented in a way that minimizes the burden on the family as much as possible. This may require gathering information about the child and family that is sometimes beyond the usual inquiry. As a result, the PCP may be perceived by families as intrusive; however, most families are able to understand this exploration of their family life once it is explained to them. For example, information about the family's routines and preferences may help in suggesting minor modifications in the type or timing of medication administration or procedures that will make the child's care less disruptive. Family members may not know on their own whether or not they can safely modify schedules. Tailoring care to the individual family also requires a longitudinal and developmental framework in which the management strategies and responsibilities shift over time as the parents become increasingly comfortable with the management of the condition and with the child's developmental progress.

### Involving and Preparing the Child

The PCP must provide developmentally appropriate information to the child about his or her treatment. The child should also be involved in the timing, nature of, and assent for special procedures, especially when real choices exist. As the child matures, communicating directly with the child, rather than exclusively through the parents, is important. Explanations that may have been given to a young child require expansion and revision as the child matures. Daily care routines are optimally shifted to the child as early as possible, and well before adolescence, to prepare the child to become independent and responsible for self-care and self-management. This emphasis on the child promotes individualized goal-setting processes and ensures the child's inclusion. Just as with other responsibilities, special care for the condition starts out as the parents' duty and must become the child's responsibility to the fullest extent possible. As the child ages, the PCP must also start preparing adolescents with ongoing health conditions for transitioning their care to physicians trained to care for adults.

### Coordination of Care

Families often need assistance with learning how to use different parts of the health care system and health-related services. Dealing with multiple systems, each of which has its own requirements and regulations, can be daunting. The PCP often knows about other resources in the community that can be helpful.

Coordination of care includes 2 major aspects: coordination within the parts of the health care system and coordination with other community agencies and

resources in the educational, recreational, and human services sectors. Family coalitions that range from disease-specific organizations to more general groups of parents of children with ongoing conditions, such as Family Voices ([www.familyvoices.org](http://www.familyvoices.org)) or the Federation of Children with Special Health Care Needs ([www.fcsn.org](http://www.fcsn.org)), may provide critical advice and networking. Other families in the practice who have struggled with finding resources may be willing to partner with parents of a child with the same or another condition. These arrangements vary from informal networking to formal parent-to-parent programs. In some instances, opportunities for care coordination can be found through private agencies, insurance companies, or Title V programs. However, for these care coordination efforts to be successful they must be family-centered. Familiarity with these programs and resources can be extremely helpful.

### Family-Centered Care

Family-centered care is based on *mutual beneficial partnerships between families and health care providers*, a philosophy first articulated by Shelton, Jeppson, and Johnson. It recognizes each family's strengths, regardless of the family's circumstances, and how these strengths can add positively to the family's health care experiences. The principles of family-centered care are listed in Box 51-2.

### Periodic Reassessment

At each stage in the care of a child with an ongoing condition, it is important to ensure that the family (including all the primary caregivers, whenever possible, and the older patient) and the PCP agree on the priorities and on the plan. Many programs use a written plan that outlines the next phase of care and builds on the mutual priorities. Although this step may be time consuming initially, it saves time in the long run. An agreed-upon plan may encourage adherence to therapy better than presumptive decisions that are made quickly and unilaterally. It is also important to remember that things change over time and that the plan will need to be revised as the goals and priorities for care evolve.

Children with ongoing conditions and their family members often experience more stress and difficulty in adjusting to the demands of their lives than other families. As a result, families with children with ongoing conditions are more likely than others in a physician's practice to need assistance from mental health services. It can be helpful for parents to understand that most families of children with ongoing conditions face extra stresses and may feel isolated. Knowing that they are not alone in their feelings can relieve some of that stress. Additionally, providing an opportunity for parents to talk about their challenges and find respite when needed may help prevent serious mental health concerns.

### THE ROLE OF HOME HEALTH CARE

Medical advances in treatments and technologies permit children with complex medical conditions to be cared for at home, where their social and developmental needs are better met. Children who benefit

**BOX 51-2 Principles of Family-Centered Care**

- Respecting child and family regardless of the family's social circumstances.
- Identifying and building on family strengths and identifying areas in which a given family may need support, taking into account their goals, priorities, and values.
- Exploring choices. In this era of cost cutting by insurers (private or public), the dialogue between the family and the health care team becomes even more important when parents decide that the best place for their child is at home.
- Coordinating care. The availability of a case manager to work with the family varies by payer and specific health insurance policy. The primary care physician is the most important link between the family and the case manager. Good communication among all health care providers is crucial to ensure that unnecessary barriers are not added to the care of the child at home.
- Providing flexible service. Home health care providers and agencies need to be aware and willing to accommodate the potential problems of interrupting normal family routines, loss of privacy, and the family's perceived loss of control of their daily lives.
- Communicating. Families need to be informed so they can collaborate and plan their child's care. Home health care providers need to recognize the importance of this relationship-based care and that sharing information is an essential part of it. This process includes documentation that takes into account the principles of family-centered care and the family's literacy level and language. This documentation will enhance the child's care by facilitating handoff procedures and overall communication among all the involved care providers, thus contributing to improved continuity of care.
- Providing ongoing emotional and practical support for families. This support is needed to help the family come to terms with the responsibility they have acquired, which may grow beyond the skills that they successfully learned when the child arrived at home, and to ensure that the child's developmental and educational needs are completely met.
- Providing family-to-family support. To prevent a family from feeling isolated and alone, opportunities for families to network with others whose child is at home under similar circumstances must be facilitated. This model can also serve as a source of potential respite.
- Providing respite care, which is needed to prevent burnout and child neglect.

Elk Grove Village, IL: American Academy of Pediatrics; 2002; Ahmann E. *Home for the High Risk Infant: A Family Centered Approach*. Gaithersburg, MD: Aspen Publishers; 1996.

from home health care vary widely in their need for assistive technology, and the intensity and duration of the health care needs. Variability in illness trajectory and the inability to identify a definitive prognosis present additional challenges. In addition to the increasing complexity in child illness, parents find themselves increasingly in the role of care providers in the home and community. To care for their child at home, parents must develop specialized skills and knowledge to manage the child's condition and the technology on which their child depends. High-acuity care in the home may include tracheostomy care, long-term ventilation, enteral and parenteral feeding, and the use of intravenous drugs (the latter via central lines). Thus the child's care requirements can significantly affect daily family functioning, leaving parents and caregivers physically and emotionally exhausted and isolated, with little personal time and limited financial resources.

The rapid growth of pediatric home health services since the 1980s has been attributed not only to increased survival of children with complex medical conditions, but also to pressures from payers to decrease lengths of stay and reduce the high costs associated with care. Current home health services include a wide array of services, from a single home visit for family support to the ongoing care of the ventilator-dependent child.

The exact number of children receiving home health care services is unknown, because they are a widely

diverse group, although dependence on technology is a common situation among patients discharged from a children's hospital. Despite this, home health care services are planned for only a small percentage of cases. A lack of consistency in discharge planning and few evidence-based clinical guidelines for children needing home health care services are further challenges. The groups of children who often receive in-home care services are children with cerebral palsy, technology dependent children (ie, home ventilator), and children with multiple chronic conditions.

Family-centered care should be the hallmark of care for children with ongoing conditions, but it is especially critical for children needing home care. These principles offer an opportunity for families and home health care providers to negotiate their respective roles and responsibilities. This fosters open communication and respect, thus decreasing the stress generated by the loss of privacy for the families and the lack of direct professional and supervisory guidance for the home health care providers, which is always available in an inpatient setting. The plan of care should take into consideration an open, honest dialogue with the parents so that they can truly understand the issues that they will encounter once the child is home, including arrangements for respite care and ways to incorporate the child's care into the family's activities with minimal interruptions. Transition planning for the discontinuation of home services needs to be an ongoing process as the child's condition progresses

and medical needs evolve. This termination of home health care services typically occurs because of insurer coverage limits or when such services are no longer clinically necessary. However, in some cases, the child's needs never lessen to the extent that home care can be discontinued. Issues relevant to the delivery of home health services are reviewed in the following sections, but specific clinical guidelines relevant to a particular disease process or condition are outside the scope of this chapter.

### Who Are Pediatric Home Health Care Providers?

Pediatric home health care providers encompass a wide range of licensed professionals whose skills and expertise support the child's health and developmental care needs and the needs of the family. Among these professionals are nurses, physical and occupational therapists, speech-language pathologists, social workers, child life specialists, and physicians. Nursing care may be provided by registered or licensed practical nurses. They may serve as direct care providers in the home and also participate in care coordination for the child and family.

Home-based physical therapy is indicated for homebound patients with rehabilitative or habilitative therapy needs or for children who qualify for early intervention. The physiatry team (which may include physical, occupational, or speech therapists) is responsible for developing short- and long-term goals, for periodically assessing the child, and for providing the family with an individualized home therapy program. The goals of the program need to be reviewed regularly with the health care team and the family. Speech therapy is indicated for children with speech and hearing impairment, who have undergone tracheostomy, or who have feeding issues. Feeding therapy can also be provided by occupational therapists with specialized knowledge and skills in facilitating feeding and swallowing using guidelines for occupational therapy practice. Medical social workers can help the parents navigate through fragmented and complicated health care and educational systems and can also connect the parents with community resources. The medical social worker should communicate regularly with the PCP. Unfortunately, many payers do not reimburse families for medical social work services.

The PCP monitors the quality of care provided in the home, coordinates the child's medical care, and makes referrals to subspecialists and early intervention programs, in addition to being responsible for the development of an individualized health care plan. Conversations with the family and the medical professionals involved in planning and providing the child's care should encompass both health and developmental care needs. The PCP should communicate the child's health care and developmental needs to local early intervention (under IDEA), and both the child's regular and special education programs (504 plans) as part of providing high-quality health care.

Subspecialist physicians involved in the child's care should also be active members of the child's home health care team, as needed. The many professionals

involved in the provision of home health care highlight the critical importance of collaboration among the family and the providers, and the need for strong interprofessional coordination. Clear delineation of the medical professional responsible for each specific aspect of a child's home health care treatment plan (eg, changes in the child's feeding tolerance or respiratory status) is necessary to avoid confusion and to ensure that issues can be addressed appropriately and in a timely fashion.

### Family-Directed Home Health Care

An alternative for parents of some of these children is family-directed home health care. Instead of a nurse being the child's primary caregiver at home, the family takes on this responsibility after proper medical training. The child's PCP, specialists, family, and local support services work together as a team to keep the child at home. Churches, schools, and social service agencies often help out by providing trained caregivers. Family-directed home health care can provide a child with a chronic condition with the benefit of a loving home environment. However, crucial to its success is consistent, ongoing communication between doctors and parents.

Several factors contribute to the growing importance of family-directed health care. In an attempt to control costs, payers frequently reduce or limit benefits. This is further compounded by a shortage of nurses and other personnel trained to work with children in a community- or hospital-based home health care program. As many state Medicaid programs are engaging in health system redesign to reduce health care expenditures, families are being offered a choice between family-directed services and traditional home health care service delivery. As an example, family-directed services for a child with developmental disabilities in Idaho allows families to use their child's individualized Medicaid budget (based on the child's strengths and assessed needs) to purchase and direct the services and supports the child receives ([www.familydirected.dhw.idaho.gov](http://www.familydirected.dhw.idaho.gov)).

In the family-directed model of home health care, the parent or other primary caregiver assumes responsibility for selecting and determining the roles of professional health care and support providers. For family-directed home health to succeed, a detailed home health care plan must be developed, with the parents, physicians, health care team, and home health care providers all working together. This type of home health care must provide some ancillary services and ongoing maintenance, just as in nurse-directed home health care programs. In this model, one of the essential roles of the PCP is to address the caregiver's needs and abilities. The physician must work with the family to ensure that the home health care plan is being followed and the established goals and resource needs are being met. A definitive respite care plan should be determined before a crisis or emergency arises. These arrangements can include other family members, community-based respite care, personal care attendants, and out-of-home medical day care. In some instances, and as a last resort, the child may have to be rehospitalized. The latter should occur only when the

family can no longer safely care for the child. For this model to succeed, a true parent-payer-pediatrician relationship should be developed, with the identification of a willing PCP being a crucial first step. Other issues that need to be addressed include defining roles and responsibilities, creating an ongoing communication plan, evaluating available community resources, identifying educational resources, and obtaining reimbursements by payers.

### **Paying for Pediatric Home Health Care**

#### **Public Funding**

Children and youth with special health care needs require health care coverage that is universal, continuous, adequate, and affordable. However, there are major gaps in the current system of health care coverage and financing that cause significant problems in accessing care for CYSHCN and financial hardship for their families. According to the National Survey of Children with Special Health Care Needs, over one-third of insured families report that their child's coverage is inadequate to pay for the services they need, and 18% say their child's health condition has caused their family financial problems.

Private insurance varies greatly in type and amount of coverage. For children who need long-term care, insurance benefits are quickly exhausted, and parents must seek other resources. One such resource is Medicaid. Eligibility for Medicaid is determined by each state and is based on family income levels. Physicians need to familiarize themselves with the eligibility criteria of the state in which they practice. In 1981, certain Medicaid eligibility requirements were waived so that every technologically dependent child could be cared for at home. This became known as the *Katie Beckett Waiver*. Physicians should also be familiar with their local and state waiver programs.

#### **Supplemental Security Income**

Supplemental security income is a cash benefit for people with disabilities and is administered by the Social Security Administration. Determination of eligibility takes into consideration finances of the family of a child younger than 18 years and disability criteria related to the child's condition. For a child, the criteria are based on the child's ability to engage in age-appropriate activities. Supplemental security income is another way of becoming eligible for Medicaid, depending on the family's circumstances and income.

#### **Early and Periodic Screening, Diagnosis, and Treatment**

The EPSDT program is a mandated Medicaid service limited to individuals younger than 21, and it ensures comprehensive pediatric health services, with an emphasis on prevention. It requires that all diagnostic and treatment services be available to an EPSDT recipient, which means that under this program, even specific services not included under a state's Medicaid plan must be made available to an EPSDT recipient.

Under the Affordable Care Act (ACA), enacted in 2010, states are encouraged or required to adjust benefits in numerous ways. Significantly, early periodic

screening, diagnosis, and treatment (EPSDT) became available to more children in 20 states beginning in 2014, because Medicaid eligibility for children ages 6 to 21 increased in those states to 250% of the federal poverty level, shifting children from Children's Health Insurance Program (CHIP) to Medicaid. Two states, Arkansas and Iowa, received waivers allowing them to enroll 19- and 20-year-olds into adult programs, although EPSDT requirements must be fulfilled. The remaining states already covered these older children under Medicaid. Depending on the benefits covered by their state's CHIP program, these children may also become newly eligible for assistance with nonemergency transportation for medical appointments. Another important service change under the ACA is that families of terminally ill children enrolled in Medicaid or CHIP may elect to receive hospice care without having to forgo potentially curative care.

Medicaid benefits are described in each state's plan, which must be approved by the Centers for Medicare and Medicaid Services. Home health care is among the mandatory services covered by Medicaid. However, private-duty nursing is an optional service that is not mandated, and its availability may vary from state to state.

#### **Medicaid Managed Care Organizations**

Managed care organizations receive contracts from Medicaid. To obtain these contracts, organizations must demonstrate an adequate network of health care providers and offer a vast array of services. This system is based on providing primary care for the beneficiaries. The child's PCP coordinates the necessary care and makes all the needed referrals, including referral for home health care services. While these organizations may have incentives to restrict services, it should be noted that fee-for-service reimbursement systems have incentives to increase services. Neither system is perfect for children with ongoing conditions. An important new concern with the insurance exchanges created under the Affordable Care Act is that some plans may not have adequate levels of specialized care providers in network to provide for children with rare conditions, and therefore families may need to obtain services at high out-of-pocket cost outside of their networks.

This system has built-in disincentives and barriers, and the requirements vary from state to state. Patients may be moved automatically from one plan to another without being aware of it, necessitating a change in PCPs. This movement among plans may interrupt the continuity of care for these patients.

#### **Medical Day Treatment Programs**

Parents of children who have complex medical needs face a myriad of challenges. They must provide direct, around-the-clock care and coordinate multiple therapies and medical appointments while managing their other family, personal, and work-related responsibilities. Demands on families such as administering medications and therapies, maintaining equipment, and providing transportation to appointments may require that parents cut down their work hours or give up a job. As reported in the 2009–2010 National

Survey of Children With Special Health Care Needs Chartbook, families of 37.2% of children with special health care needs devote 1 to 4 hours per week providing and coordinating care for their children. Thirteen percent of families spend 11 hours a week or more managing these tasks. Medical day treatment programs offer many clinical and personal advantages for these families.

As more children with medically complex health conditions and varied technology support needs survive to school-age and young adulthood, interdisciplinary programs are evolving and adapting into hybrid settings that provide educational placement alternatives for children whose needs are too complicated to allow them to attend regular school. Children are able to continue to meet school expectations in an environment that provides the required medical and emotional interventions. Comprehensive programs integrate disease management and self-care in conjunction with therapeutic activities in an outpatient setting that provides the intensity of inpatient medical care. This approach provides children and their families an increased sense of independence, confidence, and control over the illness. High-quality, cost-effective pediatric medical day treatment can facilitate faster rehabilitation, reduce rehospitalizations, reduce homebound isolation, and supply a cost-effective alternative to traditional home health care.

As in all home health care programs, a written individual health plan needs to be developed, and the communication between all members of the health care team is an essential ingredient.

## EMERGENCY AND DISASTER PREPAREDNESS

Electrotechnology-dependent children and young adults comprise a unique, extremely high-risk group during an emergency or disaster. These children and youth may be technology dependent for life support or maintenance of activities of daily living. The inability to use required devices because of an electrical failure and lack of back-up generator power could jeopardize a patient's life. Electrical devices can fail for a variety of reasons aside from those associated with a natural or man-made disaster. Studies have demonstrated the unrealistic expectations of families in responding to such an event, as well as the benefits of a parent-focused preparedness intervention. It is important for physicians to recognize that electricity is often taken for granted, so families should be drilled in how to prepare for and respond to a power failure.

## TRANSITION TO ADULT CARE

Transition from pediatric to adult-centered health care should be carefully planned. In youth with a chronic condition this planning is complicated and time consuming; fortunately, there are guidelines and algorithms available to assist the PCP (Figure 51-1) (see Chapter 66, Transitions to Adulthood).

### Definition

The goal of transition is “to maximize lifelong functioning and potential through the provision of high

quality, developmentally appropriate health care services that continue uninterrupted as an individual moves from adolescence to adulthood.” The process of transition also encompasses the consideration of future education/training, vocation, housing, medical insurance, and legal planning. Although nonmedical issues may seem beyond the realm of the PCP, families and the patient often value the PCP's advice, especially when these issues are not being addressed elsewhere.

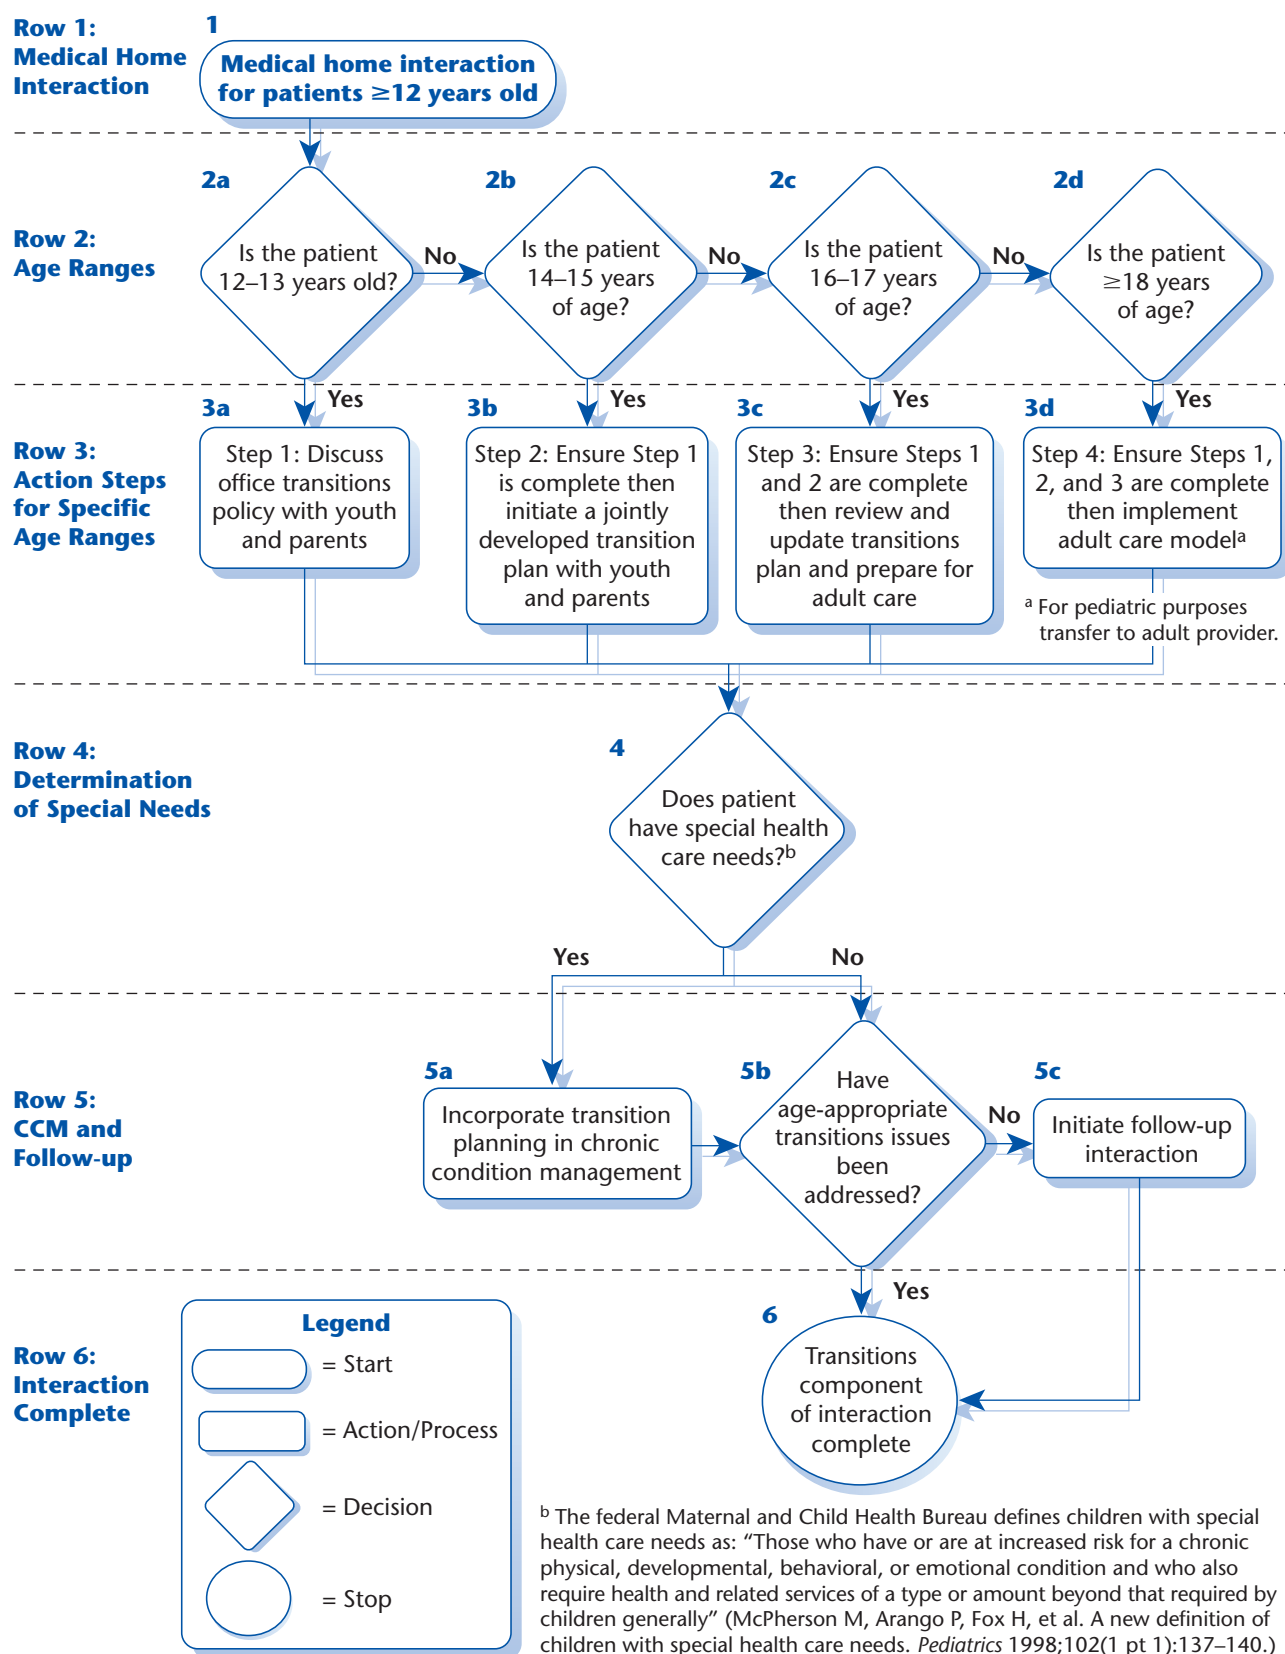

## The Scope and Complexity of Transition

Ninety percent of youth with chronic conditions survive into their adult years, making the transition to the adult medical world a reality for most. This process requires thoughtful, coordinated planning among the PCP, the family, and the youth. Finding a physician and maintaining medical insurance are 2 major hurdles youth with chronic conditions face. Adjustment to the differences between the pediatric and adult models of care is often difficult, but is easier if the adolescent is able to begin taking a more active part in care prior to the formal transition. Dependency, cognitive impairment, psychosocial immaturity, and conditions that affect mental health may present additional challenges.

Youth with chronic conditions are at risk for dependency on their families because of their ongoing medical needs and the tendency for families to overprotect them. Some have intellectual delays or lower cognitive levels inherent to their conditions or experience learning problems because of lost school time during prolonged or frequent hospitalizations. Medical treatments and severe complications of a disease may additionally lower cognitive levels compared to typical teens. Complications or treatment of youth with sickle cell disease, youth who are liver transplant recipients, youth who have had cardiac and kidney transplants, and survivors of childhood cancer are examples of conditions associated with lower IQs. Delays in psychological and social development may also be present, because of frequent hospitalizations and functional limitations that have prevented extracurricular, social, and work-related experiences. Associated mental health issues secondary to having a chronic condition can include problems with attention, anxiety, and depression. This has been described in youth with seizure disorders, sickle cell disease, and recipients of cardiac transplants.

## Management of the Transition Process

Ideally, a transition should start with the PCP who knows the patient's history well and will oversee the process, coordinating with the subspecialty medical providers and assisting the patient and family. Transition planning should start much earlier than the transfer process (when the patient actually moves to adult care). Current recommendations suggest starting the planning at age 12 or 13 and involving the teen in his or her own care more actively over time. Reasons for starting early include encouraging development of maximal independence during the ensuing years, involving the youth before the social pulls of middle adolescence, and recognizing that transition planning takes many years.

**Figure 51-1** Health care transition-planning algorithm for all youth and young adults within a medical home interaction. (From American Academy of Pediatrics, American Academy of Family Physicians, and American College of Physicians, Transitions Clinical Report Authoring Group. Supporting the health care transition from adolescence to adulthood in the medical home. *Pediatrics*. 2011;128(1):182–200.)

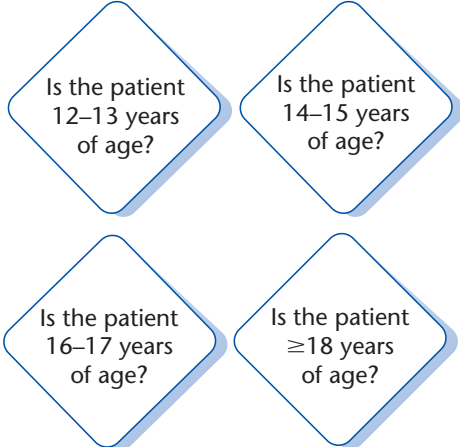

ALGORITHM COMPONENT	DESCRIPTIVE TEXT
<b>Medical home interaction for patients <math>\geq 12</math> years old</b>	<b>1.</b> Initiate first step in the health care transition planning process at age 12.
	<b>2a, 2b, 2c, 2d. Age Ranges.</b> By age 12, conduct surveillance to assess any special health care needs. Start actual transition planning by age 14. By ages 16–17, transition planning should be well established. At age 18, initiate an adult model of care for most youth, even if there is no transfer of care. If transition planning does not occur on the schedule described by the algorithm, a concentrated effort is required (eg, special visits) to successfully complete the process.
<b>Step 1:</b> Discuss office transitions policy with youth and parents	<b>3a.</b> Every practice should have a written transition policy that is prominently displayed and discussed with youth and families. The policy should explicitly state the practice's expectations and care process for the health care transition of their adolescent patients to an adult model of care.
<b>Step 2:</b> Ensure Step 1 is complete then initiate a jointly developed transition plan with youth and parents	<b>3b.</b> The practice should use a standard transition plan that can be adapted for each patient's needs. This tool should include components to obtain an accurate assessment of the patient's ability to successfully transition. Providers should interview youth and family members to identify needs and to assess the intentions and motivations for youth independence.
<b>Step 3:</b> Ensure Steps 1 and 2 are complete then review and update transitions plan and prepare for adult care	<b>3c.</b> Transitions plans must be reviewed regularly and updated as necessary. The provider must also perform surveillance for changes in the youth's medical status and address youth and family concerns that may warrant changes in transition goals. Failure to achieve transition readiness goals warrants reevaluation of the existing plan, and increased frequency of medical home interventions/visits. A "pretransfer" visit to the adult medical home could be conducted during the year before the transfer.
<b>Step 4:</b> Ensure Steps 1, 2, and 3 are complete then implement adult care model <sup>a</sup>	<b>3d.</b> Transition to an adult model of care occurs appropriate for youth's developmental level. This is followed as appropriate by transfer to an adult medical home. Complete medical records should be delivered to the adult provider, along with a portable summary, which is also provided to the patient or guardian. For children and youth with special health care needs, direct communication between pediatric and adult providers is essential, as adult medical personnel may be unfamiliar with certain pediatric conditions.

Figure 51-1, Cont'd

Continued

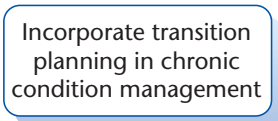

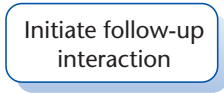

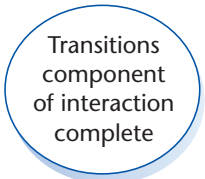

ALGORITHM COMPONENT	DESCRIPTIVE TEXT
 <p>Does patient have special health care needs?<sup>b</sup></p>	<p><b>4.</b> Transition planning for children and youth with special health care needs should include specific chronic condition management (CCM) activities such as: use of registries; care plans; care coordination; CCM office visits; and comanagement with medical subspecialists. Transition goals must be individualized to account for variations in the complexity of a youth's condition and in the youth's intellectual ability and guardianship status.</p>
 <p>Incorporate transition planning in chronic condition management</p>	<p><b>5a.</b> Youth with special health care needs require an expanded transition planning process. Transition planning in CCM includes addressing the exchange of complex health information; competencies for self-care; transfers of specialty care; and issues related to insurance entitlements, guardianship, and eligibility for adult services. In a medical home, such youth may have a written care plan as part of the medical record. At age 14, this plan should include a section titled "transition plan," which should be expanded and developed as the youth approaches age 18 and beyond.</p>
 <p>Have age-appropriate transitions issues been addressed?</p>	<p><b>5b.</b> Use of transition planning tools and readiness checklists facilitate the provider's ability to ensure that all age-appropriate transition issues have been addressed. Each action step must be completed in order, even if it means the provider has to schedule specific visits to initiate and complete steps missed earlier in the process in order to catch up before the next visit.</p>
 <p>Initiate follow-up interaction</p>	<p><b>5c.</b> Focused tasks involving little detail or complexity can be addressed by the medical home care coordinator, medical provider, or other appropriate staff through telephone or electronic media. More complex issues may necessitate face-to-face office visits.</p>
 <p>Transitions component of interaction complete</p>	<p><b>6.</b> The provider is finished with the transition tasks for that specific interaction or visit; transition planning is an ongoing activity that occurs at every interaction.</p>

Figure 51-1, Cont'd

A transition policy should be established at each practice site to provide a uniform understanding for medical providers and families. It should include the expected age of patient transfer and the responsibilities of the patient, caregivers, and medical providers before transfer. This policy should be available to patients and families to review and can be posted or provided in the form of a brochure. Examples are available at [www.gottransition.org](http://www.gottransition.org).

Assessing a patient's readiness skills and core knowledge of medical problems allows the PCP to plan steps that maximize independence and facilitate the ultimate transfer. The process should be

individualized to the patient's intellectual level and overall functioning. Various examples of readiness checklists are available. Most assess the patient's knowledge of the chronic medical condition and of medications; current level of independence in daily living activities; and individual skills, strengths, and weaknesses.

A portable medical summary and an emergency information form are helpful transition tools. An emergency information form should be filled out soon after the initial diagnosis of a chronic condition and updated regularly. It should be readily accessible in the event that a youth needs to be taken to an emergency room.

It allows efficient communication of information to providers who are not familiar with the details of a patient's chronic condition. A medical summary that can be updated regularly is an additional source of information and can be expanded into a medical transfer summary at the time of transfer to adult care. A variety of templates are available for the medical summary, and the American Academy of Pediatrics has a downloadable emergency information form at [www.aap.org/advocacy/blankform.pdf](http://www.aap.org/advocacy/blankform.pdf). Both the emergency form and medical summary should be updated in collaboration with the subspecialists who provide ongoing care, depending on the youth's condition, and can be kept on a flash drive or computer. Including these forms in the electronic medical record and updating them regularly can provide accurate communication between providers during the transition process and during transfer.

A transition plan, similar to a care plan, should discuss who provides, and who pays for, ongoing care, including education, transportation, and upkeep of equipment, if applicable. Ongoing routine medical care up until the actual transfer is also essential for the health and well-being of youth with chronic conditions and should include ensuring that immunizations are up to date and monitoring nutritional needs, exercise, sexual activity, mental health, and the use of illegal drugs, alcohol, and cigarettes. There is a tendency to avoid these routine adolescent topics in the care of patient with chronic conditions, in particular in patients with intellectual disabilities and those who are physically challenged. Youth with chronic conditions attempt to "normalize" their adolescent experience as much as possible. By ignoring inquiry about sexual activity, drugs, cigarettes, alcohol, and mental health issues (eg, suicidal ideation, depression, anger, and anxiety) the PCP will miss opportunities to provide safety advice and appropriate adolescent counseling. In many states, minors are able to provide consent for treatment for mental health problems, substance use, contraception, and sexually transmitted infections and can be seen without a parent or guardian for these issues.

Appropriate medical insurance is imperative to ongoing medical care. With current insurance regulations, youth who have medical insurance under their parents' insurance plan are able to continue until 26 years old. Many youth with chronic conditions receive Supplemental Security Income (SSI), which provides Medicaid in most states. SSI rules change dramatically when a youth turns 18 years old and may affect ongoing coverage. Before age 18, youth qualify by their physical or medical impairments and a financial assessment based on the resources of the patient's parents/guardians. At 18, qualification is determined by the youth's ability to work and by the patient's own financial resources, rather than his or her parents or guardians. One-third of youth who receive SSI lose their coverage at age 18 years, based on either disability or financial criteria. Alternately, some youth who previously were financially ineligible because of their parent's income become eligible for SSI at 18 because of the adult financial criteria applies only to their own income.

Youth with chronic conditions who qualify for special education services should have an Individualized Educational Plan (IEP). These youth will age out of special education at 21 years. Beginning at age 16 or younger, the youth should be included at a yearly IEP meeting, and a transition plan individualized to that youth's abilities should be established. Included in the transition plan should be a plan for future education, vocation or training programs, and housing. A transition linkage coordinator from the school should attend these meetings to facilitate planning (IDEA regulations guarantee transition planning, but how it is implemented may vary state to state). Making a family aware of this aspect of the school process and reviewing the plan provides the PCP with insight about the youth's level of functioning and ability to participate in the planning process. Many colleges across the United States have special programs for the inclusion of intellectually disabled youth and have offices to assist youth with learning disabilities.

Legal advice is well beyond the PCP's capability; however, it is important to understand the terminology and the importance of decision making for those youth with chronic conditions. Under HIPAA, a child's medical information is protected and thus not available to parents once that person turns 18 years. It is therefore extremely important to discuss in advance and legally determine who will be available to participate in the young adult's care after the 18th birthday. This is especially important for those individuals whose capacity (cognitive or emotional) is intermittently or continuously impaired or who have conditions that are particularly likely to cause them to be temporarily impaired and unable to make decisions for themselves. Legal documents must be prepared to deal with these issues before the actual birthday in order to clarify who can act on behalf of the youth. While it is usually clear that arrangements are necessary for someone who cannot live independently, situations in which health issues are more episodic and the level of impairment is intermittent can be more complicated. Issues such as who will take on the responsibility for the disabled youth are best decided in advance, especially as their parents are also aging. There are various degrees of legal supervision that a parent can obtain, with guardianship being the most restrictive. A less restrictive set of supports often can be put in place. Divided decision making between the youth and his or her parent(s) can be specific to health decisions or financial decisions, or tailored to that youth's needs. Examples include: conservatorship, a health surrogate, health guardianship, or powers of attorney (health and financial). In addition most hospitals expect adults (those over 18 years old) to have advanced directives. It is important to discuss advance care planning with youth who are capable of participating in such discussions. Because each state and county has different rulings related to these legal decisions, a legal consultation is important to guide a family properly.

The transition of youth with chronic conditions generally has not been a well-organized process. Unnecessary hospitalizations, medical procedures, and visits to the emergency department result from lack of coordinated transition to adult care providers.

Fortunately, beginning early and referring to pre-existing guidelines and other tools (see Box 51-3) can smooth the transitions, provide better medical care, and help ensure long-term functioning for youth with chronic conditions. The ultimate goal is to have young adults who are as independent as possible and are able advocates for their medical care.

**CONCLUSION**

Pediatric home health care has been the fastest-growing expenditure of health care in the United States, motivated by the increased survival of fragile infants and children and by managed care pressures. Despite this trend, research and studies about pediatric home health care from the PCP's perspective have lagged. More outcome studies are needed not only to develop evidence-based clinical guidelines, but also to learn how to address family issues such as barriers, access, stress levels, psychological problems, financial consequences, job absenteeism, and family satisfaction.

health care need. This likelihood may be related to the higher proportion of boys who are diagnosed with Attention Deficit Hyperactivity Disorder and other behavioral disorders. Although children with special health care needs have the same basic educational and developmental needs as their healthy peers, many have a range of problems that may interfere with their academic performance or require special medical services in school. Collaborative efforts among school personnel, health professionals, and families enhance the health, education, and development of these children and should be the basis for addressing their needs in school.

In the past, children with special health care needs were often isolated from healthy children in schools or were taught at home; they were thus deprived of crucial social contacts and a broad educational experience. Several laws now ensure that all children have access to education in the least restrictive environment.

Public Law 94-142, the Education for All Children Act of 1975, ensures a free and appropriate public education for preschool (ages 3–5 years) and school-aged children who have disabilities. The law was amended in 1990 by Public Law 101-476 and renamed the Individuals with Disabilities Education Act (IDEA). Under IDEA, children and parents are entitled to therapeutic and related services such as occupational, physical, vision, and hearing therapy; family support; social services; mental health services; educational intervention; and case management services, even if the child is not receiving special education, as long as these services relate to a child's education. Changes made to IDEA with the Individuals with Disabilities Education Improvement Act (IDEIA) of 2004 and subsequent regulations and judicial rulings have altered IDEA. Children may now be identified as having a learning disability by their response to instruction (RTI). Establishing a discrepancy between a child's ability and achievement (ie, "wait to fail") is no longer necessary to initiate psychoeducational evaluation and services. However, when conflict exists regarding what constitutes a *free and appropriate education*, the burden of proof lies with the party bringing suit (usually the parents) rather than the school district.

Section 504 of the Rehabilitation Act of 1973, appended through 1998, requires school districts to eliminate barriers that exclude children with special needs from full participation. These barriers can be either physical (buildings that are not wheelchair accessible) or programmatic (keeping children with hepatitis segregated from other children). Section 504 is, in essence, an antidiscrimination law. The definition of disability is broader under Section 504 than it is under IDEA, but fewer services are provided under 504 plans than under IDEIA. Section 504 gives students access to programs such as adaptive physical education and accommodations such as extra time for test taking. However, federal funding for remediation and school-based services such as physical therapy is only made available if a student is in special education (IDEIA). Another important distinction is that federal funding is not provided to schools under Section 504.

Under both laws, children are required to have a written plan with educational goals. This plan is called

## Chapter 52

# SCHOOL-RELATED ISSUES FOR CHILDREN WITH SPECIAL HEALTH CARE NEEDS

Karen L. Teelin, MD, MEd; Nienke P. Dosa, MD, MPH

Approximately 15% of children in the United States have a chronic physical, developmental, behavioral, or emotional condition that requires health and related services of a type or amount beyond that generally required by other children. At all grade levels, boys are 1.5 times more likely than girls to have a special

an Individual Education Plan (IEP) under IDEA and a 504 Plan under Section 504. When a child turns 16, but ideally by age 14, the IEP must include transition goals. These are appropriate, measurable postsecondary goals related to training, education, employment, and independent living skills, where appropriate. Involvement in formulating these goals is an opportunity for the pediatrician to coordinate a child's educational program with a medical treatment plan and to help families and children review beneficial services to which they are entitled. Transition planning may also include planning for a new medical provider, changes in insurance coverage, and increasing responsibility for self-care (eg, taking medications, scheduling appointments).

An up-to-date overview of relevant public laws is available on the Wright's Law Web site ([www.wrightslaw.com](http://www.wrightslaw.com)).

## SCHOOL ISSUES FOR CHILDREN WITH SPECIAL HEALTH CARE NEEDS

School provides a child with academic skills and multiple experiences critical to emotional and social development. The school-related problems and concerns that all children have can be exacerbated for a child who has special health care needs. The child's chronic condition may require frequent and, occasionally, long absences. Illness and medications may affect cognitive functioning, and physical limitations may restrict participation in school activities. These obstacles, when combined with inappropriate expectations of teachers and parents and altered interactions with peers, can provide formidable impediments to academic achievement, psychosocial development, and vocational placement.

### Medical Issues

The primary school-related goal for the pediatrician who cares for children who have chronic conditions is to ensure a safe environment. Specific issues such as transportation, special equipment, backup, and emergency plans need to be identified. Additional issues such as notification of the parents if the child's health status changes in school, responsibility for monitoring the child's health in school, and the role of the physician need to be addressed. For children who have severe or complex conditions, especially those who require technology-assisted care, a formal process of entry into school should be followed, including early notification of the school and discussion with school administrators of the child's condition and needs. The physician helps develop and approve a formal health care plan, created in collaboration with the family and child, school administration, and other health care personnel. The physician can also make recommendations regarding the program, placement, and staffing, and can participate in the training of school personnel. Excellent guides for the training of school personnel who care for children who have chronic conditions are available (see Tools for Practice at the end of this chapter). Box 52-1 lists the components of an emergency plan; Box 52-2 lists specific guidance for a child who has a chronic condition in school.

### BOX 52-1 Components of an Emergency Plan for a School Child Who Has a Chronic Condition

- Names, addresses, and telephone numbers of family and caretakers
- Emergency telephone numbers:
  - Ambulance
  - Home care company
  - Utility companies
  - Hospital
  - Emergency department
  - Primary care physician
  - Specialists
- Child-specific emergency plan
- Other school personnel to contact

### BOX 52-2 Components of Child-Specific Guidance For Care Providers

- Important personnel, including specialists and primary care provider
- Background information:
  - Conditions
  - Medical history
  - Special health care needs
  - Baseline status
  - Medications
  - Diet
  - Technological aids
  - Transportation needs
- Procedures required
- Equipment
- Child-specific techniques
- Special considerations and precautions (eg, latex allergy)
- List of possible problems for observation, reason, action
- Daily log

### School Achievement

Approximately 10% to 15% of school-aged children repeat or fail a grade in school. Children with special health care needs are nearly 3 times as likely to repeat at least 1 grade as children who have no disabilities.

The risk of school failure may be present in the earliest school years; children with special needs are significantly more likely than their healthy peers to repeat kindergarten or first grade. The pediatrician can help prevent school failure by promoting school readiness at health supervision visits, advocating for psychoeducational support, and identifying health behaviors or psychosocial factors that negatively affect school performance. Developmental concerns should be

addressed at each preventive health visit during at least the first 5 years of life. Developmental surveillance includes eliciting parents' concerns, documenting a developmental history, accurate observations of the child, and identifying risks and protective factors (eg, low birth weight or demographics). If this surveillance indicates risk, developmental screening should be conducted. In addition, screening should be conducted at all 9-, 18-, and 30-month preventive visits, using a validated, standardized tool (eg, the Parents' Evaluation of Status, or PEDS). The screening may indicate areas in which further evaluation is needed, and if so, a developmental evaluation may be indicated. Pediatricians can also promote school readiness by promoting the 5 Rs of early childhood education: reading together as a family, rhyming, routines, rewards (praise), and reciprocal and nurturing relationships. If screening tools are positive, physicians may refer appropriately. Referrals may include Early Intervention (for ages 0-3 years) or the local school system for further evaluation. Note that parents may also refer their child.

In some cases, school difficulties are caused by neurocognitive, visual, or auditory impairments. Medical treatment, such as intrathecal chemotherapy and cranial irradiation, and certain medications, such as anticonvulsants, may impair cognitive functioning. Fatigue, caused by medication or underlying conditions, should also be considered. Physicians can help identify the cause of fatigue and may be able to treat the problem by adjusting medication schedules, such as with anticonvulsants, by treating the underlying condition (eg, depression, obstructive sleep apnea), or by suggesting that a rest period be incorporated into the school day.

For most children who have chronic health conditions, however, these concerns are not significant. Many children face academic adversity because of the social and psychological consequences of their condition. "Chains of adversity" can occur when the individual's physical impairments initiate a sequence of disadvantageous outcomes. Diminished expectations, lower self-esteem, fatigue, pain, and preoccupation with symptoms that often accompany chronic conditions can be associated with a decreased self-efficacy that may develop into a learned helplessness resulting in diminished expectations and efforts. This situation may be complicated by altered parental expectations that involve many aspects of the *vulnerable child syndrome* (see Chapter 189, School Absenteeism and School Refusal). Failure to understand these psychosocial complications can lead to expectations that are unreasonably high or detrimentally low. Furthermore, there is evidence now that some behavioral and developmental problems of children with chronic conditions (eg, congenital heart disease, sickle cell disease, renal failure) are rooted in associated neurologic differences.

Children who have special health care needs often have increased school absences, which may lead to significant educational disadvantage (see Chapter 189, School Absenteeism and School Refusal). Homebound teaching often becomes available only when a child misses at least 5 consecutive days of school (varies by

school system), yet most children who have chronic conditions have frequent, intermittent absences. Pediatricians can encourage parents and teachers to help keep children who are disadvantaged by absences from falling behind in school work and can advocate that a child be made eligible for homebound teaching without the usual waiting period. Homebound teaching has significant limitations, including fewer hours of instruction and lack of social contact. School attendance should be encouraged whenever possible. Medical appointments should be scheduled during nonschool hours whenever possible.

### Job Achievement and Independent Living

For most children who have special health care needs, expectations for participation in the work force as adults should be no different from the expectations for their healthy peers. Nonetheless, many children, particularly those with developmental disabilities, fail to participate fully in society once they become young adults. High school graduation rates for students who have disabilities are lower than for those who have no disabilities, and of those who graduate, fewer go on to college. Vocational rehabilitation, a federally funded, state-operated program, is an important funding stream for adolescents with disabilities seeking post-secondary education, adaptive driving skills, or employment. Because most vocational services do not become available until candidates are 18 years old, prevocational skills, including social skills training and independent living planning, should be included in a child's IEP or 504 plan during the high school years.

Schools must provide opportunities for youths to be active participants in pre-employment and employment activities from the earliest stages of the child's academic experience. Unfortunately, many youths with special health care needs enter the workforce later than their nondisabled peers. Participation in peer-appropriate activities at every stage of schooling is essential to successful transition to adulthood. Parental support and adult role models are also important.

### COLLABORATION OF SCHOOL STAFF AND HEALTH PROFESSIONALS

Collaboration among school-based educational and health personnel, community-based providers, and parents is essential in caring for the chronically ill child in school. Only through well-coordinated efforts do educators become aware of the child's medical needs and health care providers become aware of the child's learning needs.

Primary care physicians provide direct medical care and guidance about medical issues and play a vital role as advocates for their patients who have chronic conditions. As the professional who knows the child medically and psychosocially, the pediatrician can encourage academic achievement and socialization and help anticipate major transitions in a child's educational career. Not all medical diagnoses meet eligibility requirements under IDEA for special education services. The determination of eligibility may be made at the discretion of state and local education authorities. Physicians are often asked to provide notes

for home tutoring, and it is usually best to contact the school system before providing these notes. Familiarity with a child's IEP is a prerequisite for effective primary care of the child who has a chronic health condition. One example of the primary care physician's role is physician guidance in the development of an adaptive physical education program for children with special needs. The National Center on Physical Activity and Disability is a clearinghouse for guidelines for physical activity that can be used for planning an adaptive physical education program for a wide variety of pediatric conditions, such as autism and spina bifida.

Teachers and parents need to know the implications of the child's medical condition for school performance. Lack of such information can result in misunderstanding the child's medical condition, which can lead to denial of services, misinterpretation of behaviors, unnecessary restrictions, or unrealistic expectations. With adequate information, teachers and parents can foster not only academic achievement, but also social competence. Teachers can implement recommendations and provide ongoing evaluation of a child's progress. Their input is central to the IEP and invaluable to comprehensive medical management.

The school nurse usually coordinates health services in the school. In most school districts the nurse is responsible for contacting physicians and parents about a child's medical needs. Nurses also often develop and implement care plans and emergency plans in collaboration with the school pediatrician, the primary care pediatrician, or pediatric subspecialists. Federal standards for school nurses set forth in the Healthy People 2020 initiative include a nurse-to-student ratio of 1:750. Many school districts fall short of this goal, and some schools do not have a nurse on site. School nurse practice acts currently define the scope of nursing service on a state-by-state basis. School nurses are increasingly involved with public health measures such as obesity prevention and mental health screening. In addition, the number of school-based health care clinics is growing rapidly, especially in medically underserved areas. Most of these clinics have a multidisciplinary staff (eg, a physician, nurse practitioner, social worker, or health educator); their potential contribution to the care of children with special health care needs should not be overlooked.

## Chapter 53

# PHYSIOLOGY AND MANAGEMENT OF FEVER

Henry M. Adam, MD

Viewing fever as both a response to illness and a disease has a long history in Western cultures. Hippocrates perceived fever as a defense mounted by the body against an underlying disorder; the Galenic and medieval traditions understood fever to be a means of restoring balance among the humors by burning off an excess of phlegm (water) with yellow bile (fire). On the other hand, the writers of the Gospels saw fever as

the disease that Jesus “rebuked,” miraculously curing Simon’s mother-in-law.

This *double vision* regarding fever has persisted despite our relatively sophisticated understanding of the physiologic mechanisms of temperature control, blurring how we as physicians and as parents see the child who is febrile. Although our science teaches us that fever, as part of the inflammatory response, is only a sign or symptom of the real pathologic process, we have the need to *treat* fever with a drug and a sponge, as if it were the noxious culprit. Fever, as opposed to hyperthermia, rarely poses a threat to a child’s well-being; in fact, the argument has been made that as an energy-expensive phenomenon, fever is not likely to have weathered evolution without conferring some survival benefit. Considering that fever is the most common signal of illness in children, serving as the chief complaint for as many as one-third of all pediatric office visits, we would do well to clarify our approach to its management, which is distinct from management of the illnesses that cause it.

## FEVER AND THERMOREGULATION

Fever is a regulated elevation of body temperature, mediated by the anterior hypothalamus, that occurs in response to an insult that stimulates the body’s inflammatory defenses. Similar to a thermostat, the hypothalamic set point controls the temperature that the body tries to maintain. Some provocation, most commonly a viral infection in children, induces macrophages to release low-molecular-weight proteins called cytokines, among them interleukin-1 and interleukin-6 and probably tumor necrosis factor, that function as endogenous pyrogens. They circulate to the anterior hypothalamus, where by increasing local levels of prostaglandin E<sub>2</sub>, they induce a rise in the set point. With the body’s thermostat now up-regulated, several mechanisms come into play to bring the core temperature (defined as the temperature of blood within the pulmonary artery) up to the new set point. Because the core temperature, even as it begins to elevate, is lower than the thermostat setting, a person developing fever feels chilled. Physiologically, the body’s response is to generate more internal heat, setting skeletal muscles to shivering and stimulating cellular metabolism while minimizing heat loss to the environment by vasoconstricting the skin and turning off sweat glands. The one phenomenon is analogous to heating up the furnace, the other to closing the windows.

Hyperthermia, on the contrary, is an unregulated rise in core temperature to a level above the hypothalamic set point, either from overproduction of heat (thyroid storm) or a reduced ability to dissipate heat (a bundled-up baby), or as with heat stroke from overexertion on a hot and humid day, which is a combination of the two. The body’s response to hyperthermia is the opposite of its response when a fever is induced; instead of an initial chill, intense flushing ensues as blood vessels in the skin vasodilate and sweat glands activate in an attempt to lose as much heat as possible to the outside. The furnace is burning out of control; the only strategy is to try to open the windows wide.

Whereas hyperthermia may raise body temperature to dangerous, even deadly, levels, fever seems to be a homeostatic process, physiologically regulated within benign limits. DuBois first noted how unusual it was, even for patients who had an untreated serious infection, to have a body temperature exceeding 106°F (41.1°C). Two studies, one retrospective and the other prospective, that examined large numbers of children who came to emergency departments were consistent in finding that in only 0.05% of visits did the child have a temperature of 106°F or higher. Although the pediatric literature conflicts about whether a temperature greater than 106°F (frequently called hyperpyrexia) is a marker of particular risk for serious underlying infection, no study suggests that the elevated temperature itself poses a threat to an otherwise healthy child except in the extraordinarily rare event that body temperature exceeds 107°F (41.7°C). A child who has a temperature greater than 106°F is likely to have an element of hyperthermia, such as dehydration, in addition to fever. Evidence is accumulating that as an intrinsic feature of the febrile response, the body releases *endogenous cryogens*, peptides that counterbalance pyrogens and modulate how high the hypothalamus sets its thermostat. Vasopressin and melanocyte-stimulating hormone, as well as some of the cytokines that also may act as pyrogens, seem to help limit the height fever can reach.

As a centrally regulated response to an inflammatory insult, fever may well serve as a helpful component of the body's acute phase reaction and is an adaptive response widely present in the animal kingdom among cold-blooded and warm-blooded species. At least some species of fish and lizards, when infected, move to a warmer part of their environment, thus raising their body temperatures. This behaviorally induced fever has demonstrable survival benefit, which can be negated with antipyretic agents that lower temperature and increase mortality. Fever can retard the growth and reproduction of many invasive pathogenic microorganisms, both bacterial and viral, and it seems to lower the amount of iron that is available to invading bacteria, many of which have a greater iron requirement at higher temperatures. Among its other effects on human physiology, fever enhances neutrophil migration and the production of superoxides; it promotes T-cell proliferation and increases the release and activity of interferon. Interestingly, some of fever's apparently beneficial stimulation of immunologic function may be reversed at very high temperatures, in the hyperpyretic range.

Unfortunately, no conclusive experimental information is available to prove that fever benefits humans clinically in the course of an infection, and some data suggest that, at least within the context of endotoxemia, the metabolic cost of fever contributes to mortality. However, in a teleologic sense, its metabolic cost argues for fever playing some protective role in the infected host. A process that results in a 7% to 10% increase in energy expenditure for every 1°C rise in temperature is not likely to have persisted so widely in nature, among invertebrates, fish, amphibians, and reptiles, as well as among birds and mammals, for millions of years without conferring some survival advantage.

## FEVER PHOBIA

If, then, fever only rarely poses a threat to a child and may even be of benefit, why are parents and pediatricians so generally aggressive about treating it? Schmitt coined the phrase *fever phobia* when he described the prevalence of misunderstanding about fever among parents bringing their children to an inner-city clinic. He found that 58% of parents defined temperatures below 102°F (39°C) as *high*, and 16% actually believed that, if left untreated, body temperature might rise to 110°F (43.3°C) or higher. Almost every parent thought fever could cause harmful side effects, with 46% fearing permanent brain damage. Given these responses, not surprisingly, 63% of all the parents worried "lots" about the harm fever might cause their children, and 56% gave an antipyretic agent for a temperature within the normal range. For temperatures below 102°F (38.9°C), 85% of parents treated with a drug and 62% with sponging. Twenty years later, a study in Baltimore revisiting fever phobia in 2 urban hospital-based clinics documented the enduring persistence of the misconceptions and fears Schmitt had first identified.

The population Schmitt described consisted mainly of medically indigent, poorly educated families. Kramer, Naimark, and Leduc essentially repeated Schmitt's study in a private practice with middle-class parents. Almost 50% defined temperatures in the normal range as fever; 43% thought that temperatures below 104°F (40°C) could be dangerous, and 15% believed that untreated fevers could rise above 107.6°F (42°C). Death, brain damage, and stroke were among the complications of fever these educated parents feared, with 20% believing that such complications might occur at temperatures below 104°F and 95% believing that they might occur at levels below 107.6°F. One in 5 of these parents would treat normal temperatures, and virtually all (97%) would treat a temperature below 104°F.

The fact that the use of medication to treat fever is so widespread is not surprising. The English, for example, administer antipyretic drugs for an estimated 68 million child-days each year. Fifty percent of the parents in Schmitt's study stated that physicians or nurses were their most important source of information about fever. This claim was given credence by a survey of members of the American Academy of Pediatrics in Massachusetts, in which 2 of 3 believed fever itself can pose a danger to children, and 25% of the responding physicians cited death and brain damage as potential complications of temperatures as low as 104°F (40°C). Almost three-fourths of the pediatricians always or often recommended treatment for fever, two-thirds of them for temperatures under 102°F (38.9°C). The children may be the ones who swallow the medicine, but the therapy seems aimed more at the anxiety of their parents and physicians than at any real danger that fever holds for them.

## DEFINITION AND MEASUREMENT

As would be expected with any physiologic parameter, no single normal value represents the gold standard for body temperature. Rather, a range of normal

values must take into account variations from person to person, fluctuations that reflect both a circadian pattern and age-related differences and disparities arising from the method and site of temperature measurement. A reading of 98.6°F (37.0°C) has traditionally been considered the *norm*; however, the average mean daily oral temperature, measured every 6 hours for 41 to 108 days, of 9 healthy young adult volunteers was 97.9°F (36.6°C), with a range of 97.5°F to 98.4°F (36.4°C to 36.9°C). Young children tend to have higher normal body temperatures than older children or adults; yet infants in the first 1 or 2 months of life are less likely than older children to develop fever with an infectious illness. Normally, body temperature is higher in the late afternoon and early evening than it is late at night or early in the morning, with a swing of as much as 3.0°F (1.7°C). Probably the temperature cited most frequently as defining fever is 100.4°F (38.0°C), measured rectally. However, given all the variables that affect a particular person's body temperature, any specific number used to define fever is arbitrary. The measurement of fever is discussed fully in Chapter 152, Fever.

## MANAGEMENT

The management of fever rightly begins well before a child becomes febrile. As a first step, pediatricians must recognize the part we have played in creating fever phobia in our patients' parents. The almost ritualistic dependence on measuring a child's temperature, even at routine encounters in which illness is not an issue, as well as readiness to recommend antipyretic therapy for any elevation of temperature, must certainly confuse parents when physicians tell them not to worry about fever itself. Offering counseling about fever when a child is already ill is not as likely to be as effective as introducing the subject routinely in the course of a health maintenance visit. The pediatrician should explain that fever is one of the body's natural responses and is not a threat in itself and that temperature will not spiral out of control to dangerous heights without treatment other than sensible care (eg, maintaining hydration and not overbundling). In identifying the underlying illness as the possible danger to the child, the pediatrician would do well to educate parents about the symptoms and behaviors that should alert them to trouble and signal the need for medical attention.

Treating fever is a question of judgment. If the source of the fever poses a threat, then obviously it must be addressed specifically. However, intervening against fever *per se* should be a decision that is individualized to each child who is febrile. By far the most common reason for treating fever is that it makes the child uncomfortable. Although on an evolutionary scale, fever surely must be beneficial, its benefit during the course of an acute illness is not so well proved as to override concern for the child's comfort. The decision to treat for comfort's sake should not be based on any particular temperature threshold, but rather on how the child looks and behaves; many children tolerate fevers to 104.0°F (40.0°C) without apparent ill effect, whereas others become cranky and restless

with a temperature barely above 100.4°F (38.0°C). In some cases, concern for a child's comfort may have to be balanced against the usefulness of a fever's pattern or persistence when making a diagnosis. At least one study has even suggested that acetaminophen's efficacy in improving a febrile child's comfort is more presumption than fact. In a randomized, double-blind, placebo-controlled trial of 225 children aged 6 months to 6 years who had acute fever, those treated with acetaminophen were somewhat more active and alert than the control group but were no different in mood, comfort, appetite, or fluid intake. The acetaminophen group's fever and other symptoms lasted as long, and at the end of the trial, parents were unable to tell with any reliability whether their child had received the drug or the placebo.

Some researchers also believe that reducing fever with a dose of antipyretic can distinguish children who appear ill only because they are febrile from children who have a seriously threatening infection. In fact, neither the magnitude of fever reduction nor a child's clinical appearance after receiving antipyretic medication can reliably distinguish serious from trivial infectious disease.

## Hyperthermia

Hyperthermia is different from fever, posing a real and immediate threat to any child suffering from heat illness. Successful treatment depends on restoring the core temperature to normal as rapidly as possible. Antipyretic agents, which work by lowering the hypothalamic set point, are not helpful because the set point is already below a rising body temperature that has escaped regulation. Physical cooling along with fluid resuscitation is the mainstay of therapy. Although a number of relatively unusual pediatric conditions can lead to hyperthermia (eg, malignant hyperthermia, autonomic neuropathies, encephalopathies, thyrotoxic crisis, toxin or drug exposures, pheochromocytoma, hypohidrotic ectodermal dysplasia), far more commonly dehydration, overbundling, and overexertion, particularly in a hot environment, are the underlying culprits in children.

## Treating the Infant

Particularly when comfort is the issue for an infant in the first few months of life, 2 factors weigh against routine use of medication for fever. The half-lives of all available antipyretics are prolonged early in infancy, making inadvertent overdose more of a problem. With their larger surface area relative to volume, infants are also more responsive to physical interventions that reduce body heat, such as removing clothing and blankets, keeping the room temperature moderate, and improving air circulation.

## Treating the Compromised Child

Although fever itself is benign in an otherwise healthy child who has a self-limited viral illness, the metabolic stress it entails may be more than an already compromised child can tolerate. Increased oxygen consumption and insensible water loss, along with tachycardia and tachypnea, can further threaten a child who is significantly anemic, septic, or in shock, as well as

a child rendered vulnerable by cardiac, pulmonary, renal, or any other systemic disease that strains homeostasis. Fever may also exacerbate an acute brain injury, either infectious or traumatic, and its effect on the sensorium may be confounding in a child who has a neurologic disorder.

### Seizures

More troublesome is defining the role of antipyretic medication in preventing febrile seizures. Children who are most at risk for febrile seizures (those 6 months to 6 years of age) are also the children who most frequently have self-limited viral illnesses. Urging parents to treat their young children's fever with an antipyretic agent will likely promote fever phobia, as well as an unwarranted fear of the risk that a febrile seizure poses. Undeniably, a convulsive episode in a young child is terribly frightening, but only very rarely is it dangerous. Aggressive attention to the possibility of a seizure with any fever will only magnify the anxiety parents already feel about both—and without any convincing evidence the strategy will work. The relationship between fever and seizures is neither clear nor predictable. The convulsive activity in a febrile seizure can, in fact, precede the fever, making causality at best uncertain. Parents are often not aware that their child has a fever until after the seizure has occurred. Some children seize with low-grade fever and not again when their temperature is high. The lower the child's temperature is with the first seizure, the greater the risk; this circumstance makes having a sense of control more difficult for parents because lower-grade fevers are hard to detect. Parents overcall fever when they use palpation, which may lead either to excessive dosing with an antipyretic drug or confirmatory rectal probes that become part of too many children's routine. Last, it is doubtful that even around-the-clock administration of acetaminophen or ibuprofen can prevent recurrence of febrile seizures. Parents deserve reassurance that another seizure is neither their fault nor a real threat to their child's well-being. In fact, the threat may come from the treatment if prophylaxis becomes too aggressive.

### Medical Management

If a fever is to be treated beyond routine attention to hydration and ambient conditions, the most sensible approach follows from understanding how the brain controls the body's temperature. When the hypothalamic set point rises, fever follows. Nonsteroidal anti-inflammatory drugs (NSAIDs), particularly aspirin and ibuprofen, are effective antipyretic agents because they lower the hypothalamic set point back toward normal by inhibiting the synthesis of prostaglandin  $E_2$ ; acetaminophen, which is a para-aminophenol derivative, indirectly does the same by inhibiting cyclooxygenase.

In most circumstances, aspirin should not be the drug of choice for children because of its reported association with Reye syndrome. When reducing fever is the principal concern, acetaminophen has the advantage of a long record of safety; it has almost no side effects, other than allergic reactions, unless ingested in toxic amounts greater than 140 mg/kg,

which is at least 10-fold greater than its therapeutic dose (10 to 15 mg/kg). Children younger than 6 years, the group most frequently febrile, are less susceptible than older children and adults to liver destruction, the major toxicity of acetaminophen poisoning. However, over the past decade growing epidemiologic evidence has implicated the use of acetaminophen as a contributing factor to the rising prevalence of asthma in children, and it has been recommended that children who have asthma or are at risk for asthma be advised to avoid acetaminophen. Concern has also been raised that using acetaminophen as prophylaxis against fever at the time of vaccination blunts the antibody response, which has important implications not only for individual children but also for public health: in particular, higher levels of antibody are needed to interrupt the asymptomatic carriage and transmission of *Haemophilus influenzae* and *Streptococcus pneumoniae*.

At its optimal dose (10 mg/kg), ibuprofen reduces fever as effectively as acetaminophen, and because its duration of action is moderately longer, it can be given every 6 hours rather than every 4 hours. However, ibuprofen's less frequent dosing has a cost. Typical of anti-inflammatory agents, ibuprofen can cause gastritis and gastrointestinal bleeding, and it inhibits platelet function; with chronic use, and most likely even acutely, it can cause nephropathy. The clinical situation determines whether ibuprofen's suppression of inflammation is a benefit or potentially an undesirable side effect. In a child who is febrile with rheumatoid disease, ibuprofen offers relief that acetaminophen cannot; a child whose fever arises from infection may well do better with the inflammatory response left intact. Other NSAIDs, with properties and side effects similar to those of ibuprofen, are coming on the market. Naproxen is available in a pediatric suspension; with its relatively long half-life, it can be given twice daily, at a dose of 5 mg/kg. Indomethacin and meloxicam are other NSAIDs available as suspensions but are not approved by the US Food and Drug Administration for the indication of fever control.

Using acetaminophen and ibuprofen in combination, either simultaneously or alternately, has become a common practice. Although the 2 together may be more effective at maintaining a lower body temperature than either drug alone, no evidence supports any clinical benefit to the combination, and the risk for toxicity may well be increased.

### Physical Cooling

As an alternative to medication, physical cooling can lower the body temperature of a child who is febrile, but the physiologic mechanism of fever explains why the result may paradoxically make the child feel worse. With fever, the hypothalamic thermostat is set above normal, dictating that the body will generate heat. Whereas acetaminophen or NSAIDs push the thermostat back down, damping the impulse to produce heat, physical measures such as sponging work the opposite way; in effect, they open the windows to let heat escape without adjusting the thermostat at all. As cooling begins, the hypothalamus senses

wider divergence between its own set point and the body's actual temperature; to close the gap, it sends out the directive to generate still more heat, with muscular shivering and a rise in the general metabolic rate. Aside from how uncomfortable the child may feel, with the set point remaining high after the sponging is finished, the temperature is likely to renew its climb.

Of course, under some circumstances, physical cooling has a place. Some fevers that warrant intervention clinically may not respond to antipyretic drugs, as in a neurologically impaired child whose temperature control is aberrant. If an underlying illness gives special urgency to reducing the metabolic stress that comes with a fever, then the combination of an antipyretic medication and cooling not only works more quickly than either alone but also makes physiologic sense; while cooling physically draws heat off, the drug lowers the set point to avert a rebound temperature rise. The same holds for the rare fever high enough to be a concern itself or for a fever that is complicated by some element of hyperthermia. When sponging a child, tepid water (approximately 90°F [32°C]) is probably best. It sets a moderate but effective gradient down from body temperature, rather than the precipitous decline colder water would induce, and it is less likely to distress the child who has a shivering response. Alcohol solutions have no place at all in the management of a febrile child because alcohol can be absorbed through the skin.

Hippocrates saw it right when, without the insights of our science, he somehow appreciated fever as part of the body's natural defense. We often do best to let nature have its way.

## Chapter 54

# MANAGING ACUTE PAIN IN CHILDREN

Joseph D. Tobias, MD

## INTRODUCTION

A transformation in pediatric pain management began with the rejection of previously held misconceptions that neonates, infants, and children do not feel, experience, or react to pain as adults do because of the immaturity of their peripheral and central nervous systems. These misconceptions, compounded by fears of addiction and adverse effects, led to the undertreatment of pain in both the outpatient and the hospital settings. Clinical studies have demonstrated that infants and children experience a similar severity of postoperative pain as adults and that even preterm infants demonstrate alterations in physiologic and biochemical markers of stress after painful stimuli. In fact, preterm infants respond more dramatically to nociceptive input. Although the ability to sense pain develops during the first trimester in utero, the descending inhibitory pathways that regulate the transmission of pain in the dorsal horn of the spinal cord are the last to develop. As such, this descending inhibition may be absent or underdeveloped in preterm infants.

Aside from the obvious humanitarian concerns, the inadequate treatment of pain during infancy may have long-lasting consequences, including the development of chronic pain syndromes or a heightened sensitivity to subsequent painful stimuli that may persist throughout childhood. Despite the ongoing emphasis on the need to treat acute pain, pain management in the hospital, emergency department, and outpatient setting is in many circumstances less than optimum. This reflects the need for ongoing education and scientific evaluations to determine the optimal methods of acute pain management.

Barriers to the effective treatment of acute pain in infants and children are multifactorial. In addition to wide variations in ages of the pediatric patient, several variables exist in the acute pain process that may affect treatment options and decisions. Causes of acute pain include trauma, acute medical illnesses, and surgical procedures. Pain treatment may occur in the hospital or the outpatient setting, in a tertiary care center, or in a community hospital. The child's underlying status may range from a healthy child free of systemic disease to a compromised child with several comorbid features.

## MEASURING ACUTE PAIN

The first steps in treating acute pain are to assess its severity, which may be used to guide therapy, and then assess the response to therapy. Although older children can identify when they hurt and how bad the pain is, the evaluation of preverbal children or those with cognitive impairment is difficult and can complicate the issues of pain assessment and management.

Although generalized irritability and agitation may be related to the pain, they may also be related to other factors, including parental absence or hunger. There are various pain scales and assessment tools created to overcome the problems with assessing pain. These tools range from simple, bedside checklists with 4 to 5 components that require only 5 to 10 seconds to lengthy surveys that are cumbersome and time consuming. Regardless of the clinical scenario, the child's response to the analgesic therapy must be evaluated. Pain cannot be identified if it is not assessed.

One method to evaluate children for pain is to consider the pain score to be the fifth vital sign and encourage the nursing staff to assign a pain score for all hospitalized children whenever the other vital signs are assessed. Pain is assessed to identify untreated pain even if the child is not receiving analgesics. Pain is a frequent accompaniment of many of the diseases that lead to the hospitalization of infants and children. Compliance with the use of pain scales is mandated by various hospital credentialing boards and by auditing agencies that frequently evaluate pain management protocols as a benchmark criterion.

Pain assessment tools can be categorized into self-report, observational, and physiologic scales. Many of the more involved scoring systems use components from 2 or all 3 of these types of scales. Pain assessment in the verbal child is relatively straightforward using a self-reported, visual analog score such as asking the child to identify where the pain falls on a straight line from 0 (no pain) to 10 (worst imaginable pain). These techniques rely on children's ability to assess and report their own pain. Variations of the scales aimed at being more user friendly and applicable in younger children (5 to 7 years of age) include the use of poker chips, a ladder, colored crayons, or pictures of children in varying degrees of distress. With the poker chip scale, the child expresses pain as a certain number of red poker chips (1 to 4). Mild pain would be 1 poker chip, whereas 4 poker chips would be the worst pain the child could have. The pain ladder is a picture of a ladder with 9 steps or rungs. At the bottom of the ladder is "no hurt," and at the top of the ladder is "hurt as bad as it could be." The children are then asked to point at the appropriate place on the ladder that may indicate the amount of pain they are experiencing. The severity of pain can also be expressed by selecting a colored crayon, with red indicating severe pain and blue indicating little or no pain. However, the use of colors to express pain has some variability among various ethnic groups. The association of blue with calm or no pain and red with pain does not cross all ethnic groups.

Alternatively, the child can use a *faces* scale. This self-report uses simple drawings of 6 faces with the eyes, nose, and a mouth in various positions from a smile to a frown. These faces are placed beside a corresponding 100-point vertical scale. Another scale known as the Oucher uses actual photographs of children in various degrees of distress. This scale is available with photographs of children from various ethnic groups. Both the faces and the Oucher scales are generally meant to be used as a self-report type of scoring system. However, they are sometimes modified and

the faces scale has been used as an observational tool. Pediatricians can assess the child and select the face and hence the degree of pain they think the child is feeling. A more involved assessment tool that combines both observational and self-report tools is the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS). Given its complexity, CHEOPS is more commonly used for clinical research than in actual clinical practice. The scale assigns a score of 0 to 2 for 6 categories, including cry, facial expression, verbal complaints of pain, position of the torso, whether the child is touching the wound, and position of the legs.

The assessment of pain in preverbal children or those with cognitive impairment is more difficult because these patients are unable to express the severity of the pain. The tools used in these scenarios are limited to those using observational scoring, physiologic factors, or a combination of both. Observational tools may include an assessment of the child's facial features, body positioning, and the presence or absence of crying. Physiologic parameters commonly used in pain scales include heart rate, blood pressure, respiratory rate, and oxygen saturation. Although not practical for everyday bedside use, clinical research of pediatric pain may also include physiologic parameters, including neurohumoral changes such as the alterations in the plasma concentration of stress hormones.

When a child's conditions or age preclude the use of self-report scales, several observational tools have been described and validated for neonates, preterm infants, and patients with cognitive impairment. For children with cognitive impairment, different options can be used that may be helpful in assessing their pain, including the noncommunicative children's pain checklist—postoperative version (NCCPC-PV). The NCCPC-PV includes the grading of several specific behaviors such as vocalization, socialization, facial expression, activity, body and limb positioning, and physiologic signs that have been shown to indicate pain in children with cognitive impairment. Alternatively, scales such as the face, legs, activity, cry, and consolability (FLACC) scoring system, which is used for preverbal children, can be modified for cognitively impaired children by adding specific descriptors and parent-identified behaviors for each individual child. These tools have excellent interobserver reliability and are quick and easy to use even in a busy clinical practice.

Effective pain management first identifies children in pain and includes an ongoing assessment of the response to the therapy. The tool chosen for use is not as crucial as its standard use in all hospitalized children.

## PHARMACOLOGIC MANAGEMENT OF ACUTE PAIN

Treatment regimens should incorporate a graded approach (Box 54-1) similar to what has been used for the treatment of cancer-related pain, regardless of the cause of pain. Although a primary assessment of the severity of pain is made to guide initial therapy, if

**BOX 54-1 Analgesic Ladder for Managing Acute Pain****MILD PAIN**

NSAIDs, acetaminophen, or salicylates

**MODERATE PAIN**

1. NSAIDs or acetaminophen with weak opioid (oxycodone, hydrocodone)
2. Intravenous opioids (with addition of fixed-interval NSAID or acetaminophen)
  - a. Intravenous opioid by PCA
  - b. Continuous infusion of opioid with as-needed rescue doses of opioid
  - c. Fixed, interval dosing of opioid
3. Regional anesthetic techniques

**SEVERE PAIN**

1. Continue fixed interval dosing of NSAID or acetaminophen
2. Intravenous opioid by PCA
3. Regional anesthetic techniques

NSAID, Nonsteroidal anti-inflammatory drug; PCA, patient-controlled analgesia.

effective analgesia is not achieved with the approach rung of the ladder, then the pediatrician must consider moving up to the next step. Selecting an analgesic also depends on the setting in which the pain is treated. Outpatient management requires nonintravenous routes, including oral administration, whereas the inpatient setting provides an appropriate scenario for the administration of parenteral opioids. Treatment with a nonopioid analgesic agent such as a prostaglandin synthesis inhibitor (acetaminophen, acetylsalicylic acid, or a nonsteroidal anti-inflammatory drug [NSAID] such as ibuprofen) is used for mild pain such as that after a soft tissue surgical procedure or that caused by a mild medical illness such as pharyngitis or otitis media. Moderate pain such as that after a bony orthopedic procedure or a fracture can usually be controlled with a combination of a prostaglandin synthesis inhibitor and a weak opioid (eg, an acetaminophen with oxycodone or hydrocodone). Although codeine was previously a commonly used agent, genetic variation in its metabolism to morphine results in significant variations in its effects. It is poorly metabolized in up to 30% of children, resulting in inadequate pain relief. Of even more concern, in up to 10% of some African and Middle Eastern populations, ultrarapid metabolism can lead to respiratory depression and death from increased serum concentrations of morphine. The US Food and Drug Administration (FDA) released a warning regarding its use in August 2012 and it is no longer recommended for use in children. More severe pain such as sickle cell vaso-occlusive crisis, major burns, or the pain after a major surgical procedure (thoracotomy or an exploratory laparotomy) generally requires either a regional anesthetic technique or parenteral opioids.

**Mild to Moderate Pain in the Outpatient Setting (Prostaglandin Synthesis Inhibitors and Weak Opioids)**

With tissue disruption, fatty acids are released from cell membranes and are metabolized to prostaglandins. This results in local inflammation and pain by stimulating the free nerve endings of C and A fibers. NSAIDs, acetaminophen, and salicylates inhibit the enzyme cyclooxygenase, thereby blocking prostaglandin formation. In contrast to opioids, the prostaglandin synthesis inhibitors demonstrate a ceiling effect such that, after a specific plasma concentration is achieved, increasing the dose provides no further analgesia. Although most of these agents are available as over-the-counter medications, they represent an effective and relatively safe means of controlling mild to moderate pain. The prostaglandin synthesis inhibitors include para-aminophenol derivatives (acetaminophen), NSAIDs (ibuprofen), and salicylates (acetylsalicylic acid and choline magnesium trisalicylate).

**Role of Prostaglandin Synthesis Inhibitors**

The role of the prostaglandin synthesis inhibitors to treat acute pain includes their use as the sole agent for minor pain, their combination with weak opioids for oral administration to control moderate pain, and their addition to parenteral opioids and regional anesthetic techniques for severe pain. In the last situation, their use does not replace opioids but rather provides adjunctive analgesia, thereby lowering the total amount of opioid required. Because most of opioid-related adverse effects are dose related, decreasing total opioid consumption plays a significant role in decreasing or preventing opioid-associated adverse effects.

**Route of Administration of Prostaglandin Synthesis Inhibitors**

Although prostaglandin synthesis inhibitors are most frequently administered orally, obstacles to effective analgesia may exist with this route, including a delay in the onset of analgesia, decreased bioavailability when compared with parenteral administration, refusal to take the medication, vomiting, and an inability to give enteral medications because of an ileus or abdominal complaints. Acetaminophen and ibuprofen are the most commonly prescribed medications of this class. Both medications are available in several preparations, including chewable tablets and elixirs. Acetaminophen is also available in suppository form and sustained-release tablets. An intravenous preparation of acetaminophen has recently received approval by the FDA and is available in the United States.

**Specific Uses of Prostaglandin Synthesis Inhibitors**

Acetaminophen, a para-aminophenol derivative, has a significant role in managing acute pain. Phenacetin is no longer used because of its toxicity profile and the risk for renal papillary necrosis. The association of Reye syndrome with salicylates, combined with the diverse array of NSAIDs on the market, has markedly

reduced the use of aspirin products. Despite the limited use of salicylates, the role for choline magnesium trisalicylate remains, which combines the analgesic advantages of a salicylate with limited effects on platelet function. It is an effective choice in children with qualitative and quantitative platelet issues. Table 54-1 outlines the more commonly prescribed prostaglandin synthesis inhibitors for children. In the perioperative setting, the oral premedication (midazolam) can be combined with either acetaminophen (10 to 15 mg/kg) or ibuprofen elixir (10 mg/kg). This technique provides the child analgesia on awakening and masks the taste of the midazolam premedication. If preoperative administration is not chosen, then an acetaminophen suppository (40 mg/kg) can be placed after anesthetic induction. Rectal administration means a larger dose of acetaminophen is required to achieve analgesic plasma concentrations of 10 to 20 mcg/mL. Suggested doses for acetaminophen in neonates and infants were derived from 6 pediatric acetaminophen dosing studies.

Another possibility for perioperative pain management is the postoperative administration of either ibuprofen or acetaminophen when the child complains of pain in the recovery room. This approach is valued in the outpatient setting when the physician is confronted with a child in acute pain. Waiting until the child complains is less desirable in the perioperative setting because the onset activity of any of these agents after oral or rectal administration is 20 to 30 minutes. If intravenous access is established, then small, incremental doses of an intravenous opioid (fentanyl 0.5 mcg/kg, morphine 0.02 mg/kg, or nalbuphine 0.02 to 0.04 mg/kg) are titrated every 3 to 5 minutes to provide immediate analgesia while waiting for the onset of the oral or rectal acetaminophen or ibuprofen. These doses can be repeated incrementally until the desired level of analgesia is achieved. Although dosing guidelines may list the dose of morphine as 0.1 mg/kg, it makes sense to use small, incremental doses and administer the dose at 3 to 5 minute intervals until effective analgesia is achieved. When the child is ready for discharge home, ongoing analgesia can be provided

with either acetaminophen or ibuprofen. Although administering these agents on an as-needed basis is common, fixed-interval dosing may provide more effective analgesia. Fixed-interval dosing is the administration of the medication around the clock for the first 24 to 48 hours without waiting for the child to complain of pain. For this purpose, acetaminophen (10 to 15 mg/kg) every 4 hours or ibuprofen (10 mg/kg) every 6 hours can be used. If the child is receiving acetaminophen as a fixed-interval dose and has breakthrough pain, then a supplemental dose of ibuprofen can be administered, and vice versa. Fixed-interval dosing is also recommended when opioids are used in the treatment of severe pain (see discussion later in this chapter). By maintaining a plasma concentration of the prostaglandin synthesis inhibitor, a synergistic effect is achieved, and pain can be managed with a decreased total dose of opioid.

When fixed-interval acetaminophen is administered, the pediatrician must ensure that the infant or child is not receiving acetaminophen in other forms, such as cold medicines. Additionally, given that several different acetaminophen preparations are available from numerous manufacturers, ensuring that the parents and the pediatrician know the concentration of acetaminophen or ibuprofen in the specific product is equally important. The most common cause of acetaminophen toxicity in children younger than 10 years remains inadvertent overdosing by parents.

### Role of Weak Opioids

Aspirin or acetaminophen can be combined with a weak opioid such as tramadol, oxycodone, or hydrocodone for the outpatient treatment of moderate pain or when NSAIDs alone fail to control mild pain. Although it was frequently used in the past, codeine should not be administered to children. As noted earlier, there is genetic variation in its metabolism. A hepatic microsomal enzyme metabolizes codeine to morphine for a significant part of its analgesic effect. In a cohort of 96 children, 47% had genotypes associated with low activity of the enzymes necessary for the conversion of codeine to morphine, and in 36% of

**Table 54-1** Potency and Half-Life of Opioids

OPIOID AGONISTS	POTENCY (RATIO COMPARED WITH MORPHINE)	HALF-LIFE	ACTIVE METABOLITES
Morphine	1	2–3 hr	Yes
Meperidine	0.1	2–3 hr	Yes
Hydromorphone	5–8	2–3 hr	No
Oxymorphone	10	1–4 hr	No
Methadone	1	12–24 hr	No
Fentanyl	100	20–30 min	No
Sufentanil	1000	20–30 min	No
Alfentanil	20	10–15 min	No
Remifentanyl	100	5–8 min	No
<b>AGONIST-ANTAGONISTS</b>			
Butorphanol	5	2–4 hr	No
Nalbuphine	1	4–5 hr	No
Pentazocine	0.3–0.4	2–3 hr	No

the patients, neither morphine nor its metabolites were detected. The authors concluded that the reduced ability to metabolize codeine may be more common than previously reported and that codeine analgesia is less reliable than morphine. More important, excessive amounts of morphine may be produced in those children who are ultrarapid metabolizers. This has resulted in deaths with codeine use. Given these concerns, there is no role for the use of codeine for any indication in the pediatric population.

Several of these weak opioid preparations are available in both liquid and tablet formulations. The use of a liquid or tablet is determined by the child's age and preference. For younger children, acetaminophen with oxycodone elixir (Roxicodone) is a frequently chosen option, with dosing based on the oxycodone component (0.1 to 0.15 mg/kg every 4 to 6 hours). Alternatively, if the child has recently received acetaminophen, an oxycodone elixir can be used. For older children, oxycodone and hydrocodone can also be administered as a tablet in combination with either acetaminophen or acetylsalicylic acid. Hydrocodone (7.5 mg) is also available as a tablet combined with 200 mg ibuprofen (Vicoprofen). As noted previously, the dose should be based on the oxycodone or hydrocodone component, starting at 0.1 to 0.15 mg/kg (maximal starting dose 5 mg) every 4 to 6 hours. Regardless of the preparation used, with dose escalation, the amount of acetaminophen may exceed the maximal recommended dose of 60 to 90 mg/kg/day. When higher doses of the opioid component are needed, switching to preparations that contain oxycodone or hydrocodone without the acetaminophen or aspirin is best to prevent the possibility of acetaminophen toxicity. A sustained-release formulation of oxycodone (OxyContin) is also available, which allows an analgesic plasma concentration to be maintained with a dosing interval of every 8 to 12 hours. Although used occasionally to achieve a baseline steady-state plasma concentration of opioid to provide analgesia after major operative procedures, given its abuse, diversion potential for illegal use, and a lack of data regarding its pharmacokinetics in children, the risk-to-benefit ratio of such regimens must be considered.

Tramadol (Ultram) is a unique analgesic agent with a dual mechanism of action, including agonism at the  $\mu$ -opioid receptor and inhibition of norepinephrine and serotonin reuptake in the central nervous system. Although initially thought to have limited abuse potential, clinical experience has demonstrated an abuse potential that may be similar to that of other weak opioids. Tramadol's potency is roughly equivalent to that of meperidine. An intravenous intraoperative dose of tramadol (2 mg/kg) decreases the need for rescue opioid analgesia in the recovery room in children receiving tramadol. Tramadol is well tolerated and provides effective pain relief. Tramadol analgesia is rated as very good or excellent by 69% of parents and 70% of children. Adverse events are mild or moderate and similar in incidence to that seen with other oral opioids. Tramadol has a longer half-life (6 to 7 hours) than other oral agents and an active metabolite with a half-life of 10 to 11 hours. The active metabolite is renally excreted and can accumulate in

children with renal insufficiency or failure, making it a poor choice in this setting. Despite its longer half-life, tramadol fails to decrease analgesic needs after discharge when compared with placebo. The adverse effect profile of tramadol is similar to that of other opioids (see later discussion); however, as with meperidine, a unique adverse effect generally seen only with large doses or in children with renal failure is seizure activity. Respiratory depression may be less with equipotent doses of tramadol when compared with other weak opioids.

Throughout the world, tramadol is available in injectable solution, suppository, liquid, and tablet formulations. A tablet containing 50 mg of tramadol and the combination of 37.5 mg of tramadol with 325 mg of acetaminophen in a tablet (Ultracet) are the only 2 preparations available in the United States. The 50 mg tablet is scored and can be cut in half, allowing its administration to smaller children. The manufacturer's recommendations for dosing include 0.5 to 1.0 mg/kg (initial maximal dose of 50 mg) every 4 to 6 hours as needed. However, doses up to 2 mg/kg have been used in some pediatric trials.

### Moderate to Severe Pain, Inpatient Setting (Prostaglandin Synthesis Inhibitors)

In the inpatient setting, the options for controlling acute pain are more diverse, including the option for the use of parenteral prostaglandin synthesis inhibitors and opioids. Even when the choice is made to use parenteral opioids, the prostaglandin synthesis inhibitors have a role in controlling pain because they can be used to decrease the total postoperative opioid requirements and thereby opioid-related adverse effects.

Although a significant amount of literature exists regarding the use of the parenteral agent ketorolac (Toradol), less expensive alternatives, including oral ibuprofen and acetaminophen, may also be beneficial. In patients receiving opioids, the addition of either ibuprofen (10 mg/kg orally every 6 hours) or acetaminophen (10 to 15 mg/kg orally or rectally every 4 hours) on a fixed-interval schedule is suggested. Children receiving rectal ibuprofen (40 mg/kg/day) after inpatient surgery have lower pain scores and decreased opioid requirements in the recovery room during the day of operation and the first 72 hours after the procedure. Additionally, the incidence of opioid-related adverse effects is lower in children receiving ibuprofen. Although rectal preparations of ibuprofen are not available in the United States, similar results have been reported in both children and adults with the use of rectal indomethacin or acetaminophen.

When oral or rectal administration is not feasible, intravenous administration is possible using the parenteral NSAID ketorolac. Although preliminary clinical trials suggested that ketorolac was as effective as opioids in treating acute pain, its more applicable clinical role is similar to that of other NSAIDs as an adjunct to opioid analgesia during the postoperative period. Ketorolac may also be effective in acute pain of other causes, including inflammatory and musculoskeletal pain, such as in children with pleuritic pain or vaso-occlusive crisis caused by sickle cell disease.

Ketorolac (0.5 mg/kg) demonstrated similar pharmacokinetic properties in children ranging from 1 to 16 years as in adults. A plasma concentration in the adult therapeutic range is maintained for 6 hours in most patients. More recent work has demonstrated similar clearance in infants and toddlers ranging from 6 to 18 months and those from 2 to 6 months of age.

After its initial release (recommendations for ketorolac dosing included 1 mg/kg up to 60 mg), many physicians have decreased the maximum dose to 15 or 30 mg.

To date, data regarding the analgesic efficacy of ketorolac in children younger than 1 year of age are limited. In one study, daily morphine requirements ( $0.04 \pm 0.05$  versus  $0.15 \pm 0.06$  mg/kg/day,  $P < .01$ ) were significantly decreased in 10 infants who received ketorolac. No differences in pain scores were noted between the 2 groups, and no adverse effects related to ketorolac were noted. Another study reported no adverse renal or hematologic effects in a retrospective review of ketorolac use in 53 children younger than 6 months of age who received at least 1 dose of ketorolac after cardiac surgery. The greatest increase in serum creatinine from baseline was 0.3 mg/dL. Four patients had minor episodes of bleeding while receiving ketorolac. However, safety concerns have been anecdotally reported by others. In a retrospective review of 57 children ranging in age from 0 to 3 months who received ketorolac, 10 (17.2%) had a bleeding event. Those who experienced a bleeding event received ketorolac at a mean of 20.7 days of life, with 70% receiving the medication at less than 14 days of age. Those without a bleeding event received ketorolac at a mean of 31.9 days ( $P = .04$ ). Bleeding events correlated with glomerular filtration rate of less than 30 mL/minute per  $1.73 \text{ m}^2$  or concomitant medications in all but 1 child. The authors concluded that infants younger than 21 days and less than 37 weeks' gestational age are at significantly increased risk for bleeding events and should not be candidates for ketorolac therapy.

Other specific contraindications to the use of ketorolac include children with bleeding dyscrasias or settings in which acute hemorrhage is a concern (ie, children with abnormal coagulation function, children after trauma, children after intracranial or otolaryngologic surgery). Foster and Williams reported 2 children who developed bradycardia that was temporally related to the administration of ketorolac. Adverse effects of NSAIDs and acetylsalicylic acid generally result from the inhibition of prostaglandins distant from the sites of inflammation (Box 54-2). Acetaminophen or magnesium choline trisalicylate should be considered instead of NSAIDs in children with qualitative or quantitative platelet disorders because neither agent alters platelet function. Alterations in glomerular filtration rate with NSAIDs are uncommon, except in children with pre-existing renal dysfunction, with the concomitant administration of other nephrotoxic agents, in the presence of hypovolemia, or with prolonged administration. An additional concern with NSAIDs is the inhibition of new bone formation, and in some centers, use of these agents is restricted in children undergoing spinal fusion and other procedures in which bone grafts are used.

### BOX 54-2 Adverse Effects of Nonsteroidal Anti-inflammatory Drugs

Central nervous system effects, including headache, dizziness, drowsiness  
Nausea and vomiting  
Peptic ulcer formation  
Gastrointestinal bleeding  
Decreased glomerular filtration rate, renal insufficiency or failure  
Platelet dysfunction  
Bronchospasm  
Interaction with other medications (this effect varies from one NSAID to another)

NSAID, Nonsteroidal anti-inflammatory drug.

Recent efforts to maintain analgesia while diminishing the incidence of adverse effects of NSAIDs have focused on the use of specific isomers of the NSAIDs or agents that selectively inhibit cyclooxygenase (COX) type 2 versus type 1. Although NSAID isomers are still in the investigational phase, experience with other medications has demonstrated the potential for decreasing adverse effects while maintaining efficacy by separating the 2 enantiomers of a chiral compound. Ibuprofen is a chiral mixture of its 2 optical isomers, and animal data suggest that the S(+)-isomer may provide analgesia while having limited effects on the homeostatic COX (see discussion later in this chapter), thereby limiting its adverse effect profile.

COX type 1, referred to as the homeostatic COX, controls renal blood flow, protects the gastric mucosa, and maintains normal platelet function. COX type 2, referred to as inducible COX, is responsible for the inflammatory process. Celecoxib (Celebrex), valdecoxib (Bextra), and rofecoxib (Vioxx) were the first COX-2 inhibitors introduced into clinical use. As with nonspecific NSAIDs and acetaminophen, when used as an adjunct to opioid analgesia, these medications were effective in decreasing opioid requirements and opioid-related adverse effects. However, the enthusiasm for these agents and their clinical use have decreased dramatically after several investigations demonstrated their association with an increased risk for cardiovascular events, including myocardial infarctions.

### Strong Opioids

Several options are available when considering the use of strong opioids for treating moderate to severe pain in infants and children. The most clinically relevant differences between the opioids are their potency, duration of action, and their metabolic fate, including the presence or absence of active metabolites (Table 54-2). The opioids exhibit their end-organ effects through the interaction with specific opioid receptors ( $\mu$  or  $\kappa$ ) in the peripheral and central nervous system. Opioids may act as either pure agonists (bind and activate  $\mu$ - and  $\kappa$ -receptors) or agonist-antagonists (bind and activate  $\kappa$ -receptors while binding to, but not activating,  $\mu$ -receptors). The agonist-antagonists, including nalbuphine (Nubain),

**Table 54-2****Salicylate and Nonsteroidal Anti-inflammatory Drug Preparations Commonly Used in Acute Pain Management**

MEDICATION	PREPARATION	DOSE FORMS
Ibuprofen	Oral suspension Infant drops Chewable tablets Children's caplets Tablets	100 mg/5 mL 50 mg/1.25 mL 50 and 100 mg 100 mg 200, 400, 600, and 800 mg

Acetylsalicylic acid	Capsules Several different preparations available	400 mg —

butorphanol (Stadol), and pentazocine (Talwin), should not be administered to children who have been chronically receiving opioids because they can precipitate withdrawal symptoms. Although these agents have a decreased potential to cause repression depression, a ceiling effect also exists for their analgesia. When escalating doses for increasing or persistent pain, a limit or ceiling exists to the analgesia. Although the potency and efficacy of agonist-antagonists for severe pain is less than that of pure agonists, they are useful for mild to moderate pain when the oral administration of other agents, such as acetaminophen with codeine, is not feasible or when a more rapid onset of action is desired. One option to treating moderate pain postanesthesia is to administer a single intravenous dose of an agonist-antagonist opioid followed by a switch to an oral agent when the child is discharged home. For this purpose, nalbuphine is a good option. An additional benefit of nalbuphine is that it clinically provides more sedation than other opioids because of its effects on the  $\kappa$ -opioid receptor and therefore, in addition to providing analgesia, may provide sedation for the agitated postoperative child. The agonist-antagonists should also be considered when supplemental intravenous analgesia is required in children who are receiving or have received neuraxial (epidural or intrathecal) opioids within the previous 24 hours. The potential for respiratory depression that can occur with the combination of intravenous and neuraxial opioids is less if an agonist-antagonist is used rather than a pure agonist such as morphine.

When opioids are chosen for postoperative analgesia, three choices must be made, including the opioid to be used, the mode of administration, and the route of administration. Information to help decide which opioid is best for postoperative analgesia is relatively limited. Several acceptable alternatives are available, any of which will provide equivalent analgesia provided that equipotent doses are administered. The potential for respiratory depression is present with all of the pure opioid agonists and is not more likely with any specific opioid, provided that equipotent doses are administered.

### Choosing the Appropriate Opioid

In the acutely ill child with comorbid diseases, such as a compromised cardiovascular status, or when a risk for pulmonary hypertension exists, the synthetic opioids (fentanyl, sufentanil, alfentanil, remifentanyl) with their cardiovascular stability, beneficial effects on pulmonary vascular resistance, and their ability to blunt the sympathetic stress response may be advantageous. Because the synthetic opioids have short plasma half-lives (less than 30 minutes), they are generally administered by a continuous infusion to maintain a plasma concentration adequate to provide analgesia. No inherent advantage seems to exist in regard to any of the currently available synthetic opioids, except that fentanyl is the least expensive. Remifentanyl, metabolized by plasma esterases, has the shortest half-life of any of the synthetic opioids (approximately 10 minutes). Unlike the other opioids that depend on hepatic metabolism, no difference exists in the clearance of remifentanyl across the age ranges; thus its half-life is consistent even in neonates. Given these properties, remifentanyl has become a popular agent for intraoperative use with limited applications outside of the operating room. The synthetic opioids are also used in critically ill infants and children in the intensive care unit to provide sedation and analgesia during mechanical ventilation.

Although the synthetic opioids maintain a stable hemodynamic pattern in children with compromised cardiovascular function, alternatives such as morphine are acceptable in children with normal cardiovascular function. For most children, morphine is generally the first-line agent. The dose depends on the mode of administration chosen (Box 54-3). Because of decreased hepatic metabolism and increased permeability of the blood-brain barrier with an increased risk for respiratory depression, dosing with any opioid should start at 50% of the listed dose in infants younger than 6 months. Furthermore, the monitoring of respiratory function with continuous pulse oximetry is recommended when opioids are used in this age group or in children with compromised cardiorespiratory status. Morphine can cause venodilation and

**BOX 54-3 Morphine Dosing<sup>a</sup>**

Initial intravenous titration for acute, moderate to severe pain:

0.01–0.02 mg/kg every 5 min; titrate to effective analgesia

As-needed or fixed-interval dosing:

0.05 mg/kg every 3 hr

Continuous infusion:

0.01–0.03 mg/kg/hr

Patient-controlled analgesia:

Bolus: 0.02 mg/kg every 10 min

Infusion: 0.004–0.005 mg/kg/hr

<sup>a</sup>The doses listed are for initial doses in patients who have not previously been receiving opioids. These doses should be adjusted up or down as necessary to achieve the desired level of analgesia while limiting adverse effects. When opioids are used in infants younger than 6 months or in patients with severe systemic illnesses or other comorbid diseases that place them at risk for opioid-related adverse effects, the starting dose should be 50% of the previously listed doses. Cardiorespiratory function monitoring is suggested.

may decrease blood pressure, especially in children with hypovolemia. Additionally, morphine can cause histamine release that leads to pruritus, an adverse effect particularly common in adolescents and young adults. Morphine is metabolized in the liver to morphine-6-glucuronide (M6G), which is significantly more potent than the parent compound. Because it is water soluble, M6G penetrates the central nervous system poorly and, in most circumstances, is of little consequence. However, because M6G is cleared by the kidneys and can accumulate in children with renal failure or insufficiency and lead to respiratory depression, alternative opioids such as hydromorphone (see discussion later in this chapter), which has no active metabolites, should be considered.

Other opioids that have been used to treat acute pain include hydromorphone (Dilaudid), meperidine (Demerol), and methadone (Dolobid). Hydromorphone may be advantageous when adverse effects related to histamine release such as pruritus occur with morphine. Given that pruritus tends to be more common in adolescents and young adults, hydromorphone may be considered the opioid of choice for the control of severe pain in this population. Hydromorphone's potency is 5 to 8 times that of morphine, and therefore one-fifth to one-eighth of the morphine dose is used. Patient-controlled analgesia (PCA) solutions can be prepared such that an equipotent amount of the opioid is present in each milliliter of the solution (1 mg/mL for morphine, 1 mg/mL for nalbuphine, 0.15 mg/mL for hydromorphone, and 10 mg/mL for meperidine).

Meperidine (pethidine in Europe and the United Kingdom) is approximately one-tenth as potent as morphine and is associated with a relatively high incidence of adverse central nervous system effects, including dysphoria, agitation, and seizures. Meperidine's central nervous system toxicity, including its epileptogenic potential, results from the accumulation of normeperidine, a metabolite produced by the hepatic *N*-methylation of the parent compound. Normeperidine has a long half-life (15 to 20 hours)

and is dependent on renal clearance. High or toxic levels occur more commonly in the setting of renal failure or insufficiency with the coadministration of drugs such as phenobarbital that stimulate hepatic microsomal enzymes and with large doses (greater than 2 g/day in an adult). Because meperidine offers no particular advantage over other opioids and may in fact be less efficacious than morphine in controlling acute pain, morphine or hydromorphone is preferred.

Methadone has a potency similar to that of morphine; however, the plasma half-life is 12 to 24 hours. Its long plasma half-life provides a continuous steady-state serum concentration after a single-bolus administration, thereby providing prolonged analgesia without the need for a continuous infusion or the use of a PCA device. Intraoperatively, a single intravenous dose of 0.2 mg/kg has been shown to result in lower pain scores and a decreased need for supplemental opioid analgesic agents during the initial 36 postoperative hours. The longer duration of action offers analgesic advantages over the intermittent administration of agents with shorter half-lives and may be useful in situations in which PCA devices or continuous infusions are not available. However, the use of intravenous methadone in the acute pain setting remains somewhat investigational and is therefore limited to institutions involved in ongoing clinical trials or in the hands of investigators with significant experience with its use. Additionally, the intravenous preparation may not be readily available in many institutions.

### Deciding Mode of Administration

**INTRAVENOUS ADMINISTRATION.** After deciding which opioid to prescribe, the second decision is the mode of administration. Intravenous options include on-demand (as-needed) dosing, fixed-interval administration, continuous infusion, or PCA. To provide optimal analgesia, opioids should be administered in a manner that maintains a steady-state serum concentration. For moderate to severe pain, as-needed or on-demand administration generally does not provide adequate analgesia. A significant delay can occur from the time that the child is recognized as being in pain until the medication is drawn up, administered, and has time to take effect. The optimal mode for the delivery of opioids to provide analgesia remains PCA, which allows the patient to administer a preset amount of opioid at specific intervals. These devices may be used in children as young as 5 to 6 years.

Appropriate education is required before instituting a pediatric PCA program to avoid potential adverse effects and the ineffective use of this technique. Decisions regarding PCA include the opioid to be used, the bolus dose, the lockout interval (the time that must elapse between doses), whether a continuous or basal infusion will be used in addition to the intermittent bolus doses, and the maximal total hourly dose. Although any opioid can be used with PCA, most of the reported experience is with morphine. A common starting point for the bolus dose is 0.02 mg/kg every 10 minutes as needed; however, this level may need to be adjusted based on the child's previous exposure to opioids or comorbid disease processes.

Before initiating PCA for acute pain, effective analgesia must be obtained. To accomplish this task, an opioid is titrated in incremental intravenous bolus doses (morphine 0.02 mg/kg every 5 minutes) until the desired level of analgesia is obtained. After this level is reached, the PCA device is started. A frequent problem is that children are provided adequate analgesia in the recovery room after a surgical procedure and are then discharged to the floor only to have a significant amount of time expire until the PCA pump arrives. When this circumstance happens, the child will need to repeatedly push the PCA button to re-establish an analgesic plasma concentration of the opioid. Making arrangements for the PCA pump to be delivered to the recovery room and started before the child is discharged to the floor is ideal.

One of the relatively controversial issues regarding PCA is whether to include a low basal infusion rate in addition to the patient-administered bolus doses. The use of a basal infusion rate is thought by some experts to contradict the inherent safety factor of PCA; with the basal infusion rate, opioid is infused regardless of the patient's demands. Different results have been reported in children depending on the dose used for the basal infusion rate. When comparing PCA with and without a basal infusion rate of 0.02 mg/kg per hour, the pain scores showed no difference, and adverse effects were increased, including nausea, sedation, and hypoxemia in the patients who received the basal infusion rate. In a follow-up study, a low basal infusion of 0.004 mg/kg per hour (4 mcg/kg per hour) improved the sleep pattern compared with no basal infusion rate.

When used in its classic sense, PCA requires an awake, cooperative child who is able to comprehend its purpose and is able to push the button. Therefore its use may be limited in certain children because of underlying illness or diminished cognitive capabilities. An additional controversy regarding PCA is whether to allow the use of nurse- or family-controlled analgesia in these patient populations. When used in this fashion, the PCA device eliminates the delay in opioid administration that may occur as the nurse signs out the medication and draws it up. Equivalent levels of analgesia and equivalent opioid consumption are observed when comparing PCA with nurse-controlled analgesia, although the inherent safety factor of PCA is lost.

#### **NONINTRAVENOUS ADMINISTRATION OF OPIOIDS.**

Although most moderate to severe acute pain is treated with intravenous opioids, certain situations limit or preclude intravenous administration. Nonintravenous routes include subcutaneous, oral, transdermal, and transmucosal (sublingual, buccal, intranasal, rectal, and inhaled) administration. Many of these techniques are considered investigational and are therefore likely to have a limited role in the day-to-day management of acute pain in children. Given its rapid absorption and the ability to achieve a quick clinical effect without intravenous access, the use of intranasal fentanyl has been a popular agent and route of administration in the management of acute pain in the emergency department. The intramuscular route is strictly avoided because variability in uptake and absorption leads to

erratic serum levels and ineffective analgesia. Additionally, children often deny pain to avoid a shot.

The simplest and cheapest of the nonintravenous routes remains oral administration. Although this route is frequently chosen for outpatients, its use remains limited in hospitalized patients. The oral administration of the weak opioids, including codeine and oxycodone, is a viable option even in hospitalized children provided that the pain is considered mild to moderate. Other opioids such as morphine, hydromorphone, and methadone can be administered orally. Decreased oral bioavailability necessitates the use of larger doses. Regardless of the opioid chosen, problems that arise with oral administration include a delay in the onset of action, the need for larger doses because of decreased bioavailability, and underlying medical or surgical problems that preclude the use of the gastrointestinal tract. Although the use of these opioids through the oral route is common practice for controlling cancer-related pain in the outpatient setting, information regarding this technique for controlling moderate to severe pain in the inpatient setting is limited. A novel technique termed *oral PCA* (hydromorphone or morphine) has been used to treat acute pain related to medical illnesses.

Subcutaneous administration has generally been reserved for children with terminal cancer. However, studies suggest its efficacy for controlling acute postoperative pain. Subcutaneous administration is associated with significantly fewer hypoxemic events (oxygen saturation less than 90%) than intravenous administration. When compared with intermittent intramuscular administration of opioids, 95% of nurses preferred the subcutaneous route and 74% stated that they would give morphine more readily through the subcutaneous route compared with intramuscular administration. For subcutaneous administration, a butterfly needle or a standard intravenous catheter is inserted into the subcutaneous tissue of the thigh, abdominal wall, subclavicular area, or deltoid. Dosing regimens such as basal infusions, continuous infusions, and boluses are the same as for intravenous administration. Although the plasma concentration of the opioid during subcutaneous administration are equivalent to those achieved with intravenous administration, the peak plasma concentration is not achieved as rapidly after subcutaneous administration compared with intravenous bolus dosing. The fluid volume used to deliver the opioid should be restricted to a maximum of 1 to 3 mL/hour. The site should be changed at 7-day intervals or sooner if erythema or local tissue reaction is noted. Several different opioids can be administered subcutaneously, including morphine, hydromorphone, and fentanyl. Methadone can cause significant tissue reaction with erythema and is not recommended for subcutaneous administration.

#### **Adverse Effects of Opioids**

Several adverse effects may occur with opioids that interfere with the delivery of effective analgesia (Table 54-3). Respiratory depression is directly related to potency and occurs with all opioids; equi-analgesic doses of opioids produce equivalent degrees of respiratory depression. Factors that may predispose children to

**Table 54-3** Adverse Effects of Opioids and Treatment Strategies<sup>a</sup>

ADVERSE EFFECT	TREATMENT STRATEGY
Respiratory depression	Stop opioid Airway management as needed Naloxone 1 mcg/kg every 3 min up to 10 mcg/kg; consider use of infusion for longer acting opioids
Constipation or ileus	Stool softeners Cathartic agents Motility agent (metoclopramide)
Nausea or vomiting	Phenothiazine (promethazine 0.25 mg/kg up to 12.5 mg) 5-HT <sub>3</sub> antagonist: ondansetron (0.15 mg/kg up to 4 mg)
Pruritus	Diphenhydramine (0.5 mg/kg up to 12.5 mg) Change opioid

<sup>a</sup>Monitoring respiratory status is suggested when opioids are used with phenothiazines because of the possible potentiation of opioid-induced respiratory depression.

#### **BOX 54-4** Patients at Risk for Opioid-Related Adverse Effects

1. Infants younger than 6 months
2. Patients with severe underlying systemic illness:
  - a. Cardiorespiratory dysfunction
  - b. Hepatic insufficiency
  - c. Renal insufficiency
  - d. Altered mental status
  - e. Airway obstruction
  - f. Central or obstructive apnea
3. Concomitant use of other medications:
  - a. Barbiturates
  - b. Phenothiazines
  - c. Benzodiazepines

The presence of the problems mentioned does not preclude opioid administration. When opioids are used in these patients, 50% of the usual dose is recommended in addition to continuous monitoring of cardiorespiratory function.

respiratory depression include extremes of age, severe underlying systemic diseases, pre-existing altered mental status, and the addition of other medications that potentiate the central respiratory depressant effects of opioids (Box 54-4). The presence of these comorbid problems does not preclude the use of opioids; however, initial doses should start at approximately 50% of the usual regimens, and the monitoring of cardiorespiratory function is suggested to help provide the early identification of cardiovascular and respiratory compromise.

Respiratory depression may also occur in the setting of renal failure in children receiving morphine. Whereas morphine undergoes primarily hepatic metabolism, the metabolite M6G is dependent on renal excretion. M6G possesses respiratory depressant activity and analgesic activity several times that of the parent compound. In children with altered renal function, an opioid such as hydromorphone, which does not have active metabolites, may be a safer alternative.

In children who develop respiratory depression, the first priority remains airway management with provision of supplemental oxygen or bag-mask ventilation as needed followed by the incremental administration of naloxone. Because several different dilutions of naloxone are available, particular attention must be paid to the individual ampule. Standard pediatric ampules contain either 0.4 or 1.0 mg/mL. Naloxone should be administered in incremental doses of 1 to 2 mcg/kg, repeated every 3 minutes as needed, up to a total dose of 10 mcg/kg. The administration of small incremental doses is suggested because reversing respiratory depression is possible without reversing analgesia. Using the doses recommended in many reference texts (10 to 15 mcg/kg) will result in a precipitous reversal of all analgesia, which may lead to agonizing consequences for the patient. These large doses are used only for reversing opioid effects in the setting of an acute overdose. After respiratory depression is reversed, continued monitoring of the patient is important because the half-life of naloxone is only 20 to 30 minutes compared with 2 to 3 hours or longer for many opioids, including morphine, meperidine, or hydromorphone. Although 2 longer-acting opioid antagonists (naltrexone and nalmefene) are available, information regarding their use in children is limited.

Although the life-threatening effects of opioids such as respiratory depression are most worrisome, more commonly, the non-life-threatening problems interfere with the delivery of effective analgesia. Inadequate analgesia may occur in younger children and infants because of physicians' unfounded fears of addiction. The incidence of addiction in children receiving opioids for acute pain management is exceedingly rare. Physical dependence follows the prolonged administration (more than 5 to 7 days) of opioids and sedative agents. These problems should not limit the use of opioids but rather emphasize the need to have protocols in place that outline the options for preventing and treating such problems.

Additional adverse effects of opioids include sedation, constipation, pruritus, nausea, and vomiting. Stool softeners given concurrently with opioid therapy may help prevent constipation. Although

tolerance to some of the other adverse effects of opioids such as sedation may develop, tolerance to the opioids' effects on gastrointestinal motility does not occur. Cathartic or osmotic agents (Milk of Magnesia, 70% sorbitol) may be needed for refractory cases or when constipation has already developed. Preventing constipation with a daily dose of Milk of Magnesia during outpatient opioid therapy is easier than treating the problem after it has occurred. Children receiving opioids for acute pain are frequently inactive and may have less than normal fluid intake, which only serves to aggravate the problem of constipation. New opioid antagonists that do not cross the blood-brain barrier may soon be available. These agents may be effective in eliminating the effects of opioids on gastrointestinal motility while preserving their analgesic activity. These agents may be available in the near future for both oral and intravenous administration.

Nausea and vomiting are probably the most bothersome of the non-life-threatening adverse effects of opioids. There are 3 different mechanisms that may be involved: a direct stimulation of the central chemoreceptor trigger zone of the medulla, decreased gastrointestinal motility and increased pyloric tone, and sensitization of the vestibular apparatus. Regardless of the mechanisms involved, treatment is primarily symptomatic and may include phenothiazines, metoclopramide, 5-HT<sub>3</sub> antagonists such as ondansetron, or a new class of drug, the neurokinin-1 receptor antagonists, aprepitant, which has recently been introduced for clinical use. Phenothiazines such as promethazine are available in a preparation for rectal administration, and ondansetron has recently been released in a wafer that dissolves in the mouth. Although most experience is with the phenothiazines, adverse effects may occur with these agents, including dystonic reactions, lowering of the seizure threshold, alteration of cardiac repolarization, and potentiation of opioid-induced respiratory depression. When the phenothiazines are used to treat nausea in children receiving PCA, stopping the PCA for 30 minutes before and after the dose may be appropriate because phenothiazines potentiate opioid-induced respiratory depression. Other options to treat nausea and vomiting include metoclopramide (0.1 mg/kg up to 10 mg) or 1 of the serotonin antagonists (ondansetron, dolasetron, or granisetron). Ondansetron is administered intravenously in a dose of 0.15 mg/kg (maximum of 4 mg) intravenously every 6 hours as needed. Unlike the phenothiazines, ondansetron, dolasetron, and granisetron do not cause sedation or potentiate the respiratory depressant effects of opioids. If nausea or vomiting persists despite symptomatic treatment, then changing opioids may be helpful. No particular opioid seems to cause a higher incidence of nausea and vomiting.

Pruritus may occur as an isolated symptom or in association with urticaria. The mechanisms of opioid-induced pruritus are multifactorial and include a direct central effect as well as histamine release. Strategies to control pruritus include administering antihistamines such as diphenhydramine (0.5 mg/kg up to 12.5 mg, preferably PO to avoid excessive drowsiness) or changing to another opioid. The sedative properties

of diphenhydramine may also potentiate opioid-induced sedation. When pruritus is not controlled with antihistamines, changing to another opioid with less histamine-releasing properties may be helpful. For intravenous use, these substances include hydromorphone, oxycodone, and the synthetic agent fentanyl. Given the higher incidence of pruritus in some patient populations (adolescents, patients with sickle cell disease), initiating PCA with hydromorphone in these patients is suggested. Children with severe skin diseases such as cutaneous involvement of graft-versus-host disease may be particularly likely to develop opioid-induced pruritus. In this group of children, using fentanyl may be necessary to provide analgesia and prevent pruritus. In such circumstances, the physician should consult with the anesthesiology department or pain service for dosing guidance.

### Regional Anesthetic Techniques

Regional anesthetic techniques such as neuraxial blockade (epidural or spinal-intrathecal analgesia) or peripheral nerve blockade can be continued into the postoperative period to provide effective analgesia while preventing the potential adverse effects associated with parenteral opioid therapy. The administration of local anesthetic agents into the epidural or intrathecal space provides profound analgesia; however, undesirable side effects of the use of high concentrations of local anesthetics include blockade of the sympathetic nervous system with hypotension, urinary retention, and blockade of motor function. Epidural and intrathecal opioids can provide intense, segmental, localized analgesia without sensory, motor, or sympathetic nervous system effects. However, adverse effects of neuraxial opioids may include respiratory depression, nausea, pruritus, sedation, and urinary retention. As a result, a combination of low-dose epidural local anesthetics and opioids is commonly used to take advantage of their synergistic effects and limit the side effects of each. Fentanyl, hydromorphone, and morphine are commonly used neuraxial opioids, whereas bupivacaine and ropivacaine are the most commonly used local anesthetic agents.

The lipid solubility of the opioid predicts its clinical behavior. Fentanyl is very lipid soluble, penetrating the dura and rapidly binding to spinal cord opioid receptors, producing a fast onset of action but a short duration of action. Significant vascular absorption of fentanyl also occurs, decreasing its epidural effect and reducing its advantage over parenteral administration. Morphine is lipid insoluble and has a slower onset of action but a much longer duration of action. However, given its hydrophilic nature, morphine remains in the cerebrospinal fluid for a longer period with cephalad spread and the risks for delayed respiratory depression for up to 24 hours after neuraxial administration, thereby mandating ongoing monitoring of respiratory function during this time. Other methods of postoperative analgesia include the use of long-acting local anesthetic agents for either wound infiltration or peripheral nerve blockade. Examples of peripheral nerve blockade include brachial plexus blocks for upper extremity pain, femoral nerve blocks for femur and knee surgeries, sciatic nerve blocks for

analgesia below the knee, and intercostal nerve blocks for thoracic and abdominal surgeries. Options include the placement of a catheter to allow for continuous infusion during the postoperative period and to provide long-term analgesia for up to 3 to 5 days. Although these regional anesthetic techniques are used most commonly for the control of acute postoperative pain, they may also have applications in the treatment of acute pain of other causes. Regardless of their site of administration, attention must be paid to the dosing strategies of the local anesthetic agents to limit the potential for systemic toxicity. As such, these techniques should only be practiced by pediatric anesthesiologists with training and experience in regional anesthesia in children.

## SUMMARY

Ongoing evidence continues to demonstrate the deleterious physiologic effects of pain and the beneficial results of effective postoperative analgesia. A graded, 3-step approach is recommended with the initial therapy based on an assessment of the severity of pain. This strategy uses a combination of NSAIDs or acetaminophen, the weak opioids (codeine, oxycodone, hydrocodone), and intravenous opioids. In the setting of moderate to severe pain, acetaminophen or an NSAID should be continued on a fixed-interval basis as a means of decreasing total opioid consumption and thereby opioid-related adverse effects. Decisions regarding opioid use include the choice of opioid, route of administration, and mode of administration. For severe pain in the hospitalized child, PCA is the preferred mode of administration. Although the intravenous administration of opioids remains the primary route of administration for moderate and severe pain in the hospital setting, future formulations and developments may allow for the increased use of nonparenteral routes. Regional anesthetic techniques are frequently used to control acute postoperative pain, although these techniques may also be applicable to treat acute pain of other causes. In addition to the appropriate choice of medications, an integral aspect of pain management is the assessment of the child's pain, of the response to therapy, and of the need to increase or decrease the level of analgesia.

## Chapter 55

# MANAGING CHRONIC PAIN IN CHILDREN

Sabine Kost-Byerly, MD; Cynthia Ward, PsyD

## DEFINITIONS AND PATHOPHYSIOLOGIC MECHANISMS

The International Association for the Study of Pain defines pain as an “unpleasant and emotional experience with actual or potential tissue damage, or described in terms of such damage.” The experience requires a complex interaction of multiple processes of the nervous system: *transduction*, *transmission*, *modulation*, and *perception*. The conversion of a noxious

stimulus (mechanical, chemical, or thermal) into electrical energy by a peripheral nociceptor (free afferent nerve ending) is called *transduction*. Tissue inflammation with the release of prostaglandins, bradykinin, and a variety of other mediators can augment the receptiveness of the peripheral nerve endings. Nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and local anesthetics can reduce or inhibit the response of the nervous system at this level. The next phase of nociception is characterized by the *transmission* of information to the cell bodies of the nociceptors, the dorsal root ganglia, and to the dorsal horn of the spinal cord. Initial sharp pain is propagated through faster A- $\delta$  fibers, whereas a second, more delayed, dull, throbbing pain is transmitted through slower C fibers. Local anesthetics and  $\alpha_2$  agonists can effectively interrupt transmission. From the dorsal horn of the spinal cord and along the spinothalamic tract, excitatory neuropeptides such as glutamate (at the N-methyl-D-aspartate [NMDA] receptor) and substance P (at the neurokinin-1 receptor) can modulate the message such that it is facilitated or augmented.

Simultaneously, endogenous descending analgesic systems dampen or completely obliterate the nociceptive response. Local anesthetics,  $\alpha_2$  agonists, opioids, NSAIDs, tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and NMDA receptor antagonists can interfere with the nociceptive response at the level of modulation. Finally, when reaching the central nervous system, pain is *perceived* as an individualized unpleasant and emotional experience.

Psychological factors, such as attention, anticipation of pain, and the individual's emotional state, can influence the experience. Cognitive behavioral therapy, hypnotics, sedatives, anxiolytics, opioids, and  $\alpha_2$  agonists can ameliorate or interrupt perception.

The duration of the pain at which it should be considered chronic varies, but in general, any pain that persists for longer than 3 months is considered chronic pain. Advanced neuroimaging studies in patients with chronic pain suggest that, compared with healthy individuals, their pain processing is amplified with more intense and widespread activation of brain regions. Chronic pain can be continuous or episodic and recurrent, as in migraine headaches. Pain may last for hours, days, or even weeks but then resolve completely, only to recur at a later date. Many patients with chronic pain can have adequate pain relief with their daily management but may still experience breakthrough pain. Episodes of breakthrough pain should be assessed to identify certain patterns (eg, during physical therapy, before the next dose is due). Appropriate interventions and adjustments in therapy will prevent patient frustration and noncompliance.

## TYPES OF PAIN

Two types of pain have been identified: nociceptive and neuropathic. Nociceptive pain is most commonly associated with tissue injury or inflammation. After an injury, the painful stimulus is transmitted through the normal physiologic pathways, from the peripheral nerve ending to the central nervous system. It can originate in the musculoskeletal system as somatic

pain or in the internal organs as visceral pain. Somatic pain, such as that with osteoarthritis and rheumatoid arthritis, is often described as constant and aching. Pain caused by pancreatitis or bladder spasms is typical of visceral pain. Patients likely complain of cramping and sharp pain in these conditions.

Neuropathic pain is initiated by a primary lesion or dysfunction in the nervous system. It has a central origin when it results from an injury to the central nervous system at the level of the spinal cord or above. A typical example is pain developing after a stroke. Neuropathic pain of peripheral origin involves neural structures distal to the spinal cord. These neuropathies are caused by a multitude of conditions, such as metabolic derangements (diabetes mellitus, vitamin deficiencies), viral illnesses (herpes zoster), or toxins (chemotherapeutic agents). Independent of the origin, patients typically complain of persistent, deep aching pain, constant burning sensations, and paroxysmal cramping or lancinating pain.

Nociceptive and neuropathic pain can be associated with peripheral and central sensitization. Peripheral sensitization refers to tissue inflammation augmenting the receptiveness of the nociceptor (primary hyperalgesia). Involvement of previously unaffected afferent nerve fibers in the vicinity of the original injury (secondary hyperalgesia) may be caused by central sensitization. The combination of peripheral and central sensitization leads to an increase in the magnitude and duration of pain. In the affected area, patients might experience pain caused by a normally innocuous stimulus (allodynia), an exaggerated response to a mildly noxious stimulus (hyperesthesia), and pain in neighboring areas not originally affected by injury (secondary hyperalgesia). Proposed mechanisms to explain the characteristics of neuropathic pain include a decreased threshold of the peripheral nociceptor caused by an abnormal accumulation of sodium channels, neurogenic inflammation, and ectopic discharges in C and A- $\beta$  nerve fibers. An increased responsiveness to norepinephrine might contribute to the localized autonomic dysregulation observed in some chronic pain syndromes. In the central nervous system, hyperexcitability mediated by the NMDA receptor in the dorsal horn of the spinal cord, altered modulatory responses to a stimulus, and changes in the somatosensory cortical map of the affected body area are believed to contribute to the neuropathic pain experience.

In children, the primary care physician will encounter neuropathic pain after trauma or surgery resulting in neurologic injury. Symptoms range from continued sensitivity at the site of an incision to phantom pain after amputation. In children with cancer, peripheral neuropathic pain is common, although not always persistent, after treatment with chemotherapeutic agents such as vincristine. Neuropathic pain can also be caused by direct nerve compression by a tumor or extensive lymphadenopathy. Complex regional pain syndrome (CRPS) types 1 and 2 (formerly known as *reflex sympathetic dystrophy* and *causalgia*, respectively), once thought to be rare in children, have been described in more than 1,000 children in the literature. Particularly challenging to treat is neuropathic pain

caused by a neurodegenerative disorder or after central nervous system injury because communication with the patient and therefore assessment are often limited.

## PREVALENCE

Chronic or frequent recurrent pain disproportionately affects adolescent girls. In the United States, almost 30% of adolescent girls have reported headaches, 21% stomachaches, and 24% back pain occurring more than once a week, with 53% of these girls experiencing pain in more than 1 location. Heavy abuse of nicotine, caffeine, and alcohol was associated with these symptoms, whereas parent and teacher support was found to be protective. The prevalence of migraine headaches has been estimated to be 10% in children and up to 28% in adolescents. Children with chronic pain are more often overweight and obese than their peers, a finding associated with limitations in vigorous activities. Obese children with chronic pain experience a greater reduction in health-related quality of life than those with either one of these afflictions alone.

Daily pain in children and adolescents with life-threatening oncologic or infectious diseases such as HIV is common. Prevalence of pain is also high in patients with congenital diseases such as cystic fibrosis and Marfan syndrome, and in chronic neuromuscular or neurodegenerative processes. Intense focus on treatment of the primary disease process can result in a neglect of the illness-associated pain.

Health care use is variable: approximately 50% of children and adolescents with back pain, limb pain, and abdominal pain seek medical advice, whereas only 30% do so for headaches. Medication use, on the other hand, is much more common for headaches than for other pains. Increasing age and greater intensity and longer duration of pain, but not the frequency of pain, will bring the patient in contact with health care providers.

## EFFECT ON PATIENT AND FAMILY

Chronic pain affects the child, the child's daily life, other members of the family, and the social environment. Following the World Health Organization's model of impact of disease, the experience of chronic pain can be divided into 4 areas: *disease* or *disorder*, *impairment*, *disability*, and *handicap*. *Impairment* is assessed by taking a history and performing a physical examination. Reported symptoms such as pain, edema, or joint tenderness are a measure of the severity of the impairment. The disability caused by the disease can be evaluated by asking how the child's activities in home, school, and community are affected. Restricted involvement or inability to participate in sports or to attend school is a sign of the degree of disability. School absence has been found to be a common indicator of disability in children with a variety of conditions associated with chronic pain. Disability is influenced not only by the child's severity of pain and emotional status but also by parental coping style and expectations of teachers and school administrators. Protective parents who discourage active coping behavior in their children can unwittingly promote

withdrawal from life at school. Large schools with several thousand children can be difficult to navigate for children on crutches or in wheelchairs. Hearing from parents that school administrators advise home teaching is not unusual because accommodating the child is too time consuming. Unfortunately, removal from school can lead to *handicap*, the restriction of social roles and interactions available to the child. Children who attend school, even on a part-time basis for as little as 1 class a week, are generally easier to rehabilitate than those who have completely withdrawn from school. In these cases, the pediatrician or other physician might have to become an advocate for the child.

## EVALUATION

Pain is a subjective experience. Only patients know where, when, and how much pain they are experiencing. In infants, toddlers, and children with significant cognitive impairments, pain and discomfort after a painful stimulus are assessed indirectly by measuring changes in physiologic parameters, such as facial expressions, body movement, and intensity of crying. The Face Legs Activity Cry Consolability (FLACC) scale, although initially intended for scoring postoperative pain, is now commonly used in all clinical settings for patients between the ages of 2 months and 7 years. An adaptation of the FLACC scale is available for children with cognitive impairments. Self-report measures are appropriate for children with normal cognition who are older than 3 years of age. These tools use numbers, pictures, or words to assess pain in a graded fashion from mild to severe. The most commonly used scale for preschool-aged children is the Wong-Baker faces scale, in which a cartoon smiling face gradually changes in 5 steps to a crying face. Because of their limited vocabulary, younger children are unable to describe the particular qualities associated with chronic pain. Comparative expressions such as *crushing*, *burning*, *stabbing*, or *dull* are beyond the comprehension and lifetime experiences of younger children. For older children, in addition to numerical or visual analog scales, the pediatrician can offer a list of descriptive adjectives associated with pain and ask the child to pick several terms most representative of the pain. Location of the pain can be pointed out by the child with the help of a doll, an action figure, or the drawing of an outline of the body. Because chronic pain varies from day to day and with different activities, asking the older child to keep a pain journal is also useful. Entries into the journal should be as timely as possible because recall of intensity and frequency of pain at a later date is unreliable.

## History and Physical Examination

A thorough history and physical examination are helpful in establishing the correct diagnosis and appropriate treatment plan. A complete pain history should address the following questions:

- When was pain first noted?
- Was the onset sudden or gradual?
- Did an injury precede the pain?

- Has the pain been limited to 1 area of the body, or has it migrated?
- How often is the child in pain?
- Is the pain worse in the morning or at night?
- Is sleep affected by pain?
- How is the child's mood?

Exacerbating factors should be explored because they can point to activities to be modulated or avoided. Alleviating factors are just as important because these can be integrated into a treatment protocol. Children whose pain improves when taking a hot bath might be amenable to exploring aqua therapy as a complementary therapy.

If the child has seen other health care providers with the same concerns in the past, every effort should be made to document the quality and efficacy of previous interventions used. Medications tried should be closely evaluated for adequate dosing. It is not unusual to find that adjuvant medications such as antidepressants or anticonvulsants were stopped at too low a dose to represent an adequate trial of the medication. This circumstance only contributes to long lists of medications that the patient deems to be *not* working. On the other hand, reintroducing a previously unsuccessful treatment not only is time consuming and costly but also increases the family's frustration with the health care system.

In addition to the pain history, it is important to assess the child's functioning within his or her daily surrounding. How much assistance does the child require for taking care of personal hygiene, getting dressed, attending school, or participating in extracurricular activities? Regression to a state of dependence appropriate for an earlier developmental age is common and can lead to psychological distress and heightened family conflict.

A detailed past surgical and medical history exploring for medical and psychological comorbidities should be included. The behavioral and physical development of the child in comparison to siblings and peers might provide clues to the diagnoses of chronic pain conditions. Children with diffuse musculoskeletal pain, eventually diagnosed as benign hypermobility syndrome, may have a history of significant motor development issues in early childhood, including poor coordination, general clumsiness, and difficulties with handwriting.

Family history and social history need to be reviewed. Parents of children with chronic pain have a higher incidence of anxiety, depressive symptoms, and somatoform disorders. Certain pain syndromes, such as migraines, have long been known to aggregate in families. Children with disabilities can be at increased risk for abuse and neglect.

A thorough physical examination from head to toe is invaluable in reaching a diagnosis and designing a treatment plan. Facial expressions, body position, protective behaviors, movement, and gait can provide important information. Palpation of the head in patients with chronic or recurrent headaches might reveal tender areas. Most pediatricians are familiar with facial headaches caused by chronic or recurrent sinusitis. These headaches can have a neuropathic component because of irritation of the superior and inferior orbital nerves. Tenderness at the facial foramina of the nerves can be exquisite. A similar irritation of the

occipital nerves may be seen after posterior fossa surgeries such as a cervicomedullary decompression. Patients may suffer from headaches preoperatively and may be concerned that the procedure was unsuccessful. Tenderness at the foramen opening should be sought. Treating neuropathic pain with TCAs or anticonvulsants and referring to a pain specialist for injection of the area with local anesthetics and steroids should be considered. A patient exhibiting intolerable pain a few days after an injury such as a sprained ankle might also have hypersensitivity of the skin to even the lightest touch and an erythematous, edematous, and warm extremity. Although the pediatrician will have to consider cellulitis, the pain might also be a presentation of CRPS. On the other hand, the same syndrome may be present if the patient instead had a painful, cold, and lividly discolored extremity—with deep vein thrombosis as the differential diagnosis. The findings on the physical examination will guide further studies. A patient whose pain is initially confined to the hand or elbow may protect the arm by positioning it close to the body; the shoulder is slightly elevated, the trapezius muscle is tightened, and the head might be cocked to the side. This unnatural position leads to secondary musculoskeletal pain in the shoulder and neck region, potentially requiring a different intervention than the primary pain. Children with cognitive impairments are especially difficult to evaluate but are at risk for chronic pain syndromes caused by spasticity, scoliosis, or chronic hip dislocations. A gentle, nonthreatening examination paying close attention to changes in facial expressions or muscle tone might bring the physician closer to a diagnosis. For children who have supportive equipment such as splints and wheelchairs, the physician should take a look at the child while using the equipment. A growth spurt may turn the perfectly fitting wheelchair with chest wall supports into a compression device. Chest wall pain, back pain, or even femoral nerve and brachial plexus compression syndromes may be found on examination.

### Laboratory Evaluation

Laboratory, radiographic, and scintigraphic studies are used in children with chronic pain of unclear origin to further define a differential diagnosis (see Box 55-1). Laboratory screening tests might suggest an inflammatory or infectious process, which can help in the decision-making process and determine which specialists, if any, should be consulted. Nonspecific tests (eg, antinuclear antibodies [ANAs]) can only lead to anxiety because ANAs are found in many healthy children, particularly those with viral illnesses within the previous 3 months, and are best used as confirmatory tests for a likely diagnosis of systemic lupus erythematosus or a test to indicate the frequency of ophthalmologic exams in children with juvenile idiopathic arthritis. Three-phase bone scans can show increased or decreased uptake of the radioactive tracer. Unfortunately, these findings are only of limited diagnostic value. No consistent pattern of tracer uptake has been found to be diagnostic of a specific chronic pain condition. Nerve conduction studies and electromyography can help distinguish more diffuse cases of neuropathic

### BOX 55-1 Laboratory Evaluations to Rule Out Causes of Chronic Pain

#### LABORATORY TESTS

- Complete blood count with differential, erythrocyte sedimentation rate
- Urinalysis and urine culture

#### LABORATORY TESTS INDIVIDUALIZED ACCORDING TO INDICATION

- Stool testing and culture for polymorphonuclear leukocytes, parasites, *Giardia* species antigen
- Serum chemistry profile, amylase level
- Pregnancy test, cultures for sexually transmitted diseases
- Breath hydrogen test: lactose, fructose
- Serologic testing for amoebae, *Helicobacter pylori*

#### IMAGING STUDIES INDIVIDUALIZED ACCORDING TO INDICATION

- Abdominal and pelvic sonography
- Upper gastrointestinal contrast study with small bowel testing, abdominal computed tomography
- Upper endoscopy, colonoscopy, laparoscopy

pain from a localized nerve injury or a nerve entrapment. Quantitative sensory testing and autonomic testing are offered by a variety of pain centers. The sensitivity and specificity of the results of these studies are unclear at this point. Frequently, the main purpose of laboratory evaluation is to reassure the patient, parent, and physician of the absence of organic disease.

### Consultation

For patients with significant disability caused by their painful condition and prolonged or recurrent school absences, the pediatrician should consult with a psychologist or psychiatrist and a physiatrist. The child's functional limitations and disabilities can be better assessed and documented, a possible learning disability and school avoidance might become apparent, or presence of comorbid depression interfering with successful pain management might be diagnosed.

Once the assessment is complete, an individualized treatment plan is implemented. Age-appropriate short-term goals should be combined with long-term ones, such as walking along the shallow end of a pool without a brace, participating in a summer day camp, or obtaining a driver's license.

Dependent on a patient's individual presentation, comorbidities, or family needs, referral to other specialists should be considered early, not just for further diagnostic evaluations but also for ongoing consultation such as with an adolescent medicine specialist for a teenager or a palliative care medicine specialist for a child with cancer.

## MANAGEMENT

The goal for effective chronic pain management is a reduction of the child's pain, improvement in daily functioning, and return to age-appropriate activities.

Before initiation of any therapy, it is recommended that the pediatrician explore the child's and family's expectations. Complete pain relief may not be a realistic goal, leading to disappointment and frustration in the presence of residual pain even if the child's condition significantly improves. Instead of a simple pharmacologic intervention, multimodal therapy is usually required. Multimodal therapy can include referrals to a physical therapist, psychologist, orthopedist, rheumatologist, or other health care specialist. The pediatrician has a vital role in the process of care coordination, in concert with the family. Care coordination has been shown to improve family satisfaction and reduce health care costs. As medical home professionals, pediatricians should also assess each child's specific needs for special educational and early intervention services. Awareness of local resources and of federal, state, and local requirements is essential.

All therapies need to be weighed for their risks and benefits, particularly more aggressive interventional and surgical modalities. Many pharmacologic therapies have not been evaluated in children but have instead been extrapolated from adult management. Level 1 evidence for chronic pain therapy is virtually nonexistent in children. Benefits and potential adverse effects should be discussed in detail with the parents and child, taking the child's developmental stage into consideration.

In general, the approach to treatment of chronic pain in children is more conservative. Far fewer interventional procedures are performed in children than adults. The need for sedation or anesthesia to safely perform interventions such as a sympathetic nerve block is at least partly responsible for the more conservative treatment. Pediatricians can successfully integrate many of the therapies into their practice.

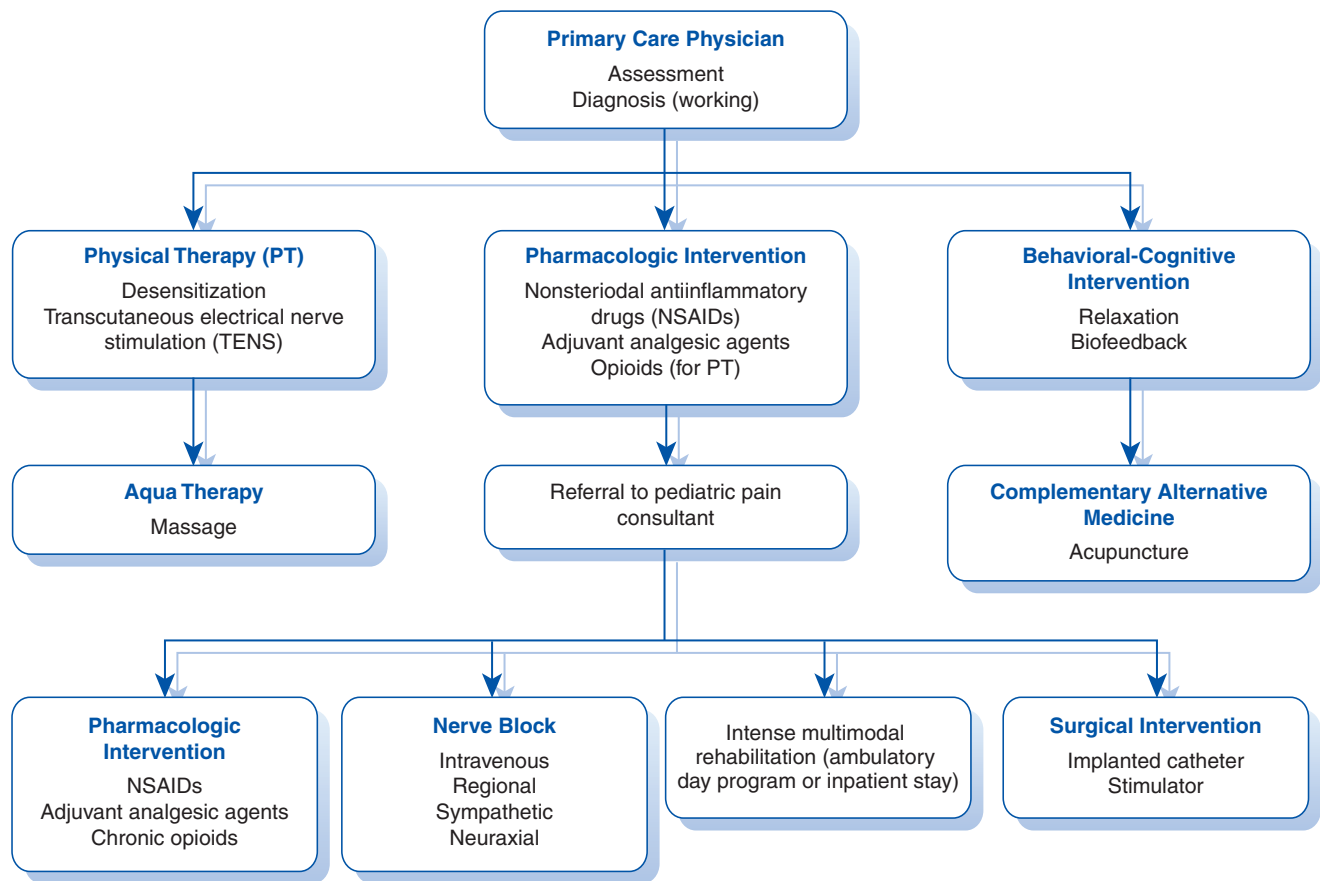

Once treatment has been initiated, continually assessing and documenting pain control and changes in function is important. Because many patients experience fluctuations in pain intensity from day to day, it is advisable to continue assessments over a longer period of time. Any positive patient and family behavior and contributions should be welcome and reinforced. Figure 55-1 highlights a possible algorithm for managing chronic pain.

### Nonpharmacologic Therapies

Ideally, nonpharmacologic therapies are fully integrated into a multimodal approach to chronic pain management in children. They should be viewed as neither something to try before "we have to get the heavy guns out" nor the last resort because "everything else we've tried has failed." Many nonpharmacologic therapies emphasize self-management skills and can improve patients' confidence in their abilities. Pediatricians can familiarize themselves with these therapies during introductory workshops or seminars offered at many professional meetings.

### Cognitive Behavioral Interventions

Cognitive behavioral interventions rely on providing age-appropriate information to the child and on the child's natural interest in imaginative play. Simple comfort measures such as swaddling, massage, and soft

**Figure 55-1** Algorithm for approach to chronic (neuropathic) pain. The pediatrician can initiate therapy. If no improvement is noted, then the patient may be referred to the pediatric pain specialist, who will continue effective modalities and add more aggressive therapy.

music are commonly used for infants, but even older children like to have their favorite stuffed animal or blanket with them in times of distress. Distraction with kaleidoscopes, bubbles, movies, or videos is appropriate for many children, even those with limited communication skills. Suggestion requires greater participation by the child. A magic item, such as a blanket, is used to lessen the pain in one area or of one procedure. The child has to be willing to be enveloped into this magic story.

Relaxation exercises offer relief to the child with chronic pain who experiences acute exacerbation of pain. Breathing techniques with deep-chest, rhythmic, or patterned breathing can be learned without professional help. Trained child-life specialists, occupational therapists, or psychologists are usually needed to explore guided imagery, progressive muscle relaxation, biofeedback, and hypnosis. Hypnosis has been found to be more effective than distraction and breathing for procedural distress in children undergoing oncologic procedures. Hypnosis and guided imagery can improve analgesia and shorten length of stay after surgery in children. Web-based cognitive behavioral interventions for patients and their families may offer an alternative to office visits in the future, potentially increasing mental health resources in areas with limited access otherwise.

### Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) consists of a battery-powered unit delivering electrical impulses to skin electrodes placed in the vicinity of the painful area. There are several theories explaining the efficacy of TENS. The gate-control theory stipulates that non-noxious impulses from TENS are transmitted through large-diameter afferent fibers. Simultaneous painful stimuli, traveling along small-diameter afferent fibers, will be suppressed at various *gates* within the spinal cord. TENS has also been suggested to activate inhibitory, descending pathways in the central nervous system because it has been associated with an increase in endogenous opioids in the serum and spinal fluid.

A variety of amplitudes, frequencies, and stimulation patterns can be programmed: low-intensity stimulation remains sensory; higher intensity will result in muscle contraction. Research evaluating the efficacy of TENS for acute and chronic pain management has been hampered by the large variety of frequencies and stimulation patterns used in studies, which makes comparisons difficult. Patients should try different patterns and intensities of stimulation to find one with which they are most comfortable. TENS appears to be most effectively used at times when pain is temporarily increased.

Adverse effects are usually limited to skin irritation, which may resolve with a switch to hypoallergenic electrode pads. TENS units should not be used together with other programmable or implantable devices (eg, pacemakers) without first contacting the manufacturers and inquiring about the safety of the combination.

### Complementary and Integrative Medicine

The use of complementary and integrative medicine (CIM) to treat chronic illness or disability is increasing in the United States. Pain was cited as the most common reason for the use of CIM in children in a recent survey. In children, the most common therapies include dietary supplements such as fish oil/omega-3 supplements, body-mind practices such as deep breathing and yoga, or body-based interventions such as massage and manipulations. The pediatrician may be asked to provide balanced advice concerning therapeutic options, although at this point only limited recommendations have been published regarding the use of CIM in the care of children with chronic illness or disability.

Acupuncture has been part of traditional Chinese medicine for more than 5,000 years. Interest in acupuncture has gradually increased during the past 30 years despite the fact that the underlying theory is different from the teachings of Western medicine: Energy (*Chi*) flows through various channels (*meridians*) in the body. Interrupting the flow leads to pathologic conditions, pain, or both. Inserting needles at particular points along the meridians can re-establish the flow of energy, thus improving or resolving the pathologic condition or pain. Acupuncture is often presumed as acceptable only to a small group of children because of the common presence of needle phobia. However, combining acupuncture and hypnosis in patients with chronic pain has been found to be highly acceptable, with a decline in anticipatory anxiety and significant improvements in pain after treatment. Further studies are necessary to assess the efficacy of acupuncture in different painful conditions.

### Pharmacotherapy

Pharmacotherapy for chronic pain includes nonopioid, opioid, and adjuvant medications. Instead of a gradual progression from nonopioids to weak opioids (disregarding the fact that at equianalgesic doses, all opioids have the same potency) and finally to strong opioids, multimodal analgesic therapy is generally preferable. The goal of such therapy is an augmentation of analgesia and a simultaneous reduction in adverse effects. Continuation of nonopioid analgesia with opioids may decrease the required dose of opioids and the incidence of opioid-related adverse effects.

Some adverse effects, such as sedation or dizziness, may be more apparent at the beginning of therapy. Initiating therapy at a low dose and titrating the dose carefully is therefore prudent. For children who attend school, weekends may be a good time to begin or augment therapy. Occasionally, an otherwise effective analgesic may require the addition of another medication to treat adverse effects such as nausea or pruritus.

Readers are referred to a more in-depth discussion of some of the listed analgesics in Chapter 54, Managing Acute Pain in Children.

### Nonopioid Analgesics

Acetaminophen has been a safe and effective analgesic for the treatment of mild to moderate pain. Administration in normal doses is well tolerated. Continuous use over many months may require lower doses. Acetaminophen is frequently an ingredient in commercially available analgesic compounds. Patients taking 1 or more acetaminophen preparations simultaneously are at risk for severe liver toxic effects.

The NSAIDs provide pain relief primarily by peripheral and central inhibition of the cyclooxygenase (COX) enzyme. Administered by the oral route, these agents are considered to be equipotent, although efficacy in individual patients may vary. The NSAIDs are particularly useful for inflammatory, bony, or rheumatic pain. Long-term administration must take the risk for gastrointestinal and renal side effects into consideration. Patients with a history of gastritis and those taking corticosteroids are generally not candidates for long-term therapy. NSAIDs that selectively inhibit one of the isoforms of COX (COX-2 inhibitors) are thought to have a lower risk for gastrointestinal adverse effects and no effect on thromboxane-induced platelet activity. In December 2004 the US Food and Drug Administration (FDA) issued a public health advisory indicating that some COX-2 inhibitors may be associated with an increased risk for thromboembolic phenomena (myocardial infarction, stroke). It remains unclear how this risk would affect children.

Whereas aspirin has largely been abandoned in pediatric practice because of its association with Reye syndrome, one aspirin-like compound with no effect on platelet function, choline-magnesium trisalicylate, continues to be prescribed in chronic pain management. The main treatment group includes patients with cancer who are experiencing bony pain and decreased platelet function. The drug is available in both liquid and tablet form and is administered twice a day. As in acute pain management, the most commonly used NSAID is ibuprofen. The limited duration of action of this drug with a required administration of 3 to 4 times a day may necessitate a switch to the longer-acting naproxen, which is administered twice a day. Dosing strategies for the most commonly prescribed nonopioid analgesics are listed in Table 55-1.

### Opioid Analgesics

Opioid analgesics are neurotransmitters that interact with several distinct receptors in the peripheral and central nervous system. The 4 major receptors are designated *mu*, *delta*, *kappa*, and *sigma*. Most currently used opioid analgesics primarily attach to the *mu* receptor. Morphine is 50 to 100 times stronger at this receptor than at the *delta* receptor. The *mu* receptor and its subspecies and the *delta* receptor are known as being related to analgesia, respiratory depression, euphoria, and physical dependence. Butorphanol attaches at a ratio of 1:4:25 at the *mu* to *delta* to *kappa* receptors.

**Table 55-1** Dosing Strategies for Frequently Used Oral Nonsteroidal Anti-inflammatory Drugs

GENERIC NAME	PEDIATRIC ORAL DOSE AND FREQUENCY	MAXIMUM ADULT ORAL DAILY DOSE	INDICATIONS	COMMENTS
Acetaminophen	10–15 mg/kg q4h	4,000 mg	Mild to moderate pain, fever	Lacks antiinflammatory activity; hepatotoxic effects at higher doses
Ibuprofen	6–10 mg/kg q6-8h	2,400 mg	Mild to moderate pain, fever, RA, OA	Oral suspension available
Naproxen	5–10 mg/kg q12h	1,000 mg	OA, RA, other rheumatic or bony pain	Oral suspension available
Salicylates (aspirin)	10–15 mg/kg q4h	4,000 mg	Mild to moderate pain, fever	Inhibits platelet aggregation, causes gastrointestinal irritability, Reye syndrome
Choline magnesium trisalicylate	8–10 mg/kg q6h	3,000 mg	Mild to moderate pain, fever	Aspirin compound that does not affect platelets

OA, osteoarthritis; RA, rheumatoid arthritis.

All opioid analgesics can be classed into agonist, antagonist, and mixed agonist-antagonist based on their receptor-binding capacities. Agonist attachment to a receptor leads to a cascade of intracellular activity, whereas antagonist attachment at the receptor does not have this response. Antagonists, such as naloxone, can competitively remove an agonist from the receptor and stop the action of the agonist. Butorphanol, a mixed agonist-antagonist, functions as an antagonist at the mu receptor and as an agonist at the kappa receptor. Therefore butorphanol, as with naloxone, can lead to withdrawal symptoms when it is used indiscriminately in patients taking mu opioids for a longer time. The most commonly used drugs are listed in Table 55-2.

Opioids are titrated to effect because response to specific opioids will vary. Tolerance with chronic administration is common, making upward dose adjustments necessary. Although mu receptor opioids are known to produce similar degrees of adverse effects, such as respiratory depression, sedation, euphoria, nausea, biliary tract spasm, and constipation, the response of particular patients will vary. If the need for dose escalation is rapid or adverse effects begin outweighing the benefits of an opioid, then the patient may be prescribed a different one, a process known as *opioid rotation*. To avoid an overdose, it is recommended to subtract 20% to 50% from the calculated equianalgesic dose when switching from one opioid to another because cross-tolerance is not completely predictable.

Most opioids for chronic pain management are administered orally. They are available as liquids of various concentrations, immediate-release tablets, and sustained-release preparations. Even for chronic pain, opioids do not always have to be administered around the clock. Providing the patient with a single dose of an opioid before physical therapy might be sufficient and might result in much better therapy. When

multiple doses of a short-acting opioid are needed throughout the day, switching to sustained-release opioids is more effective—and more convenient—because they prevent peaks and troughs in the serum and provide a better steady state. The patient's daily opioid requirement should be well known before initiating any long-acting opioids. Asking the patient and the parents to keep a journal in which they document how often a short-acting opioid was required can be helpful. This information can then be evaluated with the following questions in mind:

- Do they wake up in the middle of the night because of pain?
- Do they need medication in the middle of the school day?

Many manufacturers of sustained-release opioids provide conversion tables, but starting at lower doses than suggested and gradually titrating over several days is advisable. Immediate-release opioids can be supplemented during this period, which will avoid oversedation and drowsiness.

Methadone is currently the only long-acting opioid in liquid form. The analgesic is commonly prescribed in gradually diminishing doses for infants and children after intensive care stays with prolonged analgesic and sedative needs. Clinical guidelines for QTc monitoring during treatment with methadone have been proposed for adults but have not been formulated for children. Opioids in pill form need to be swallowed whole because chewing the pill can lead to a rapid release of the active drug and a potential overdose. Transdermal administration of the opioid is another possibility if the oral route is not available. Studies in children assessing the efficacy and safety of oral opioids lasting for up to 24 hours are lacking. Currently available long-acting opioids are listed in Table 55-3.

A child who is receiving opioids on a daily basis with generally good results might still experience an occasional escalation of pain or even daily short-lived

**Table 55-2** Dosing Strategies for Frequently Used Oral Immediate-Release Opioid Analgesics

GENERIC NAME	PEDIATRIC ORAL DOSE AND FREQUENCY	INITIAL ADULT ORAL DOSE AND FREQUENCY	INDICATIONS	COMMENTS
Codeine	0.5–1.0 mg/kg q4–6h	15 mg q4–6h	Mild to moderate pain	By mouth only. Should be avoided because effect is unpredictable. Metabolism is dependent on cytochrome P-450 enzyme, CYP2D6, which has a high degree of genetic polymorphism. Risk for overdose in ultrarapid metabolizers and no effect in slow metabolizers.
Oxycodone—immediate release	0.1 mg/kg q4–6h	5 mg q4–6h	Moderate to severe pain	Usually prescribed with acetaminophen By mouth only Less nauseating than codeine Usually prescribed with acetaminophen in adults
Morphine—immediate release	0.3 mg/kg q4–6h	5–15 mg q4–6h	Moderate to severe pain	May cause seizures in high doses Causes histamine release, vasodilation; avoid in patients with asthma. Avoid in patients with renal insufficiency because accumulation of active metabolite (M6G) may result in respiratory depression.
Hydromorphone	0.03 mg/kg q4–6h	2–4 mg q4–6h	Moderate to severe pain	
Methadone	0.1 mg/kg q6–24h (q6–8h interval: careful observation required)	2.5–10 mg q6–24h	Severe chronic pain when opioids are needed for a prolonged period Pain refractory to other opioids	QT prolongation possible in susceptible patients Toxicity caused by accumulation within 3–5 days Do not increase more often than every 5–7 days Use only in opioid-tolerant patients
Oral transmucosal fentanyl citrate		200 mcg; 200- to 1,600-mcg lozenge units	Breakthrough pain in opioid-tolerant patients	Should only be used in opioid-tolerant patients

pain, which is known as breakthrough pain. In these situations, adding a short-acting opioid to the long-acting form might be indicated, particularly when other nonpharmacologic or nonopioid measures have failed. Frequent need for a short-acting opioid in addition to the long-acting form requires a reassessment: Is the dose of the long-acting opioid too low? Is the patient more active than before therapy started? Does the patient feel only the short-acting opioid *really works*? As the serum blood level changes rapidly with the short-acting opioid, patients might experience a higher degree of euphoria and decide that only the short-acting drug helps. A frank and honest discussion of these effects can prevent unnecessary changes by the pediatrician.

Although usually reserved for oncologic and palliative care patients, long-acting opioids can be combined with intravenous patient-controlled analgesia (PCA). The PCA device is programmed without a continuous rate because the long-acting opioid provides baseline analgesia throughout the day. Intermittent

patient-initiated doses will relieve episodic pain. Occasionally, when no other intravenous fluids are administered, a low continuous rate is required to maintain the patency of the venous access.

Adverse effects associated with opioid administration, such as sedation, drowsiness, nausea, and vomiting, can be apparent during the first few days when opioids are initiated but often resolve in patients taking opioids in the long term. Increases in dose may be accompanied by a temporary recurrence of adverse effects. Reaction time can be slowed even when the patient does not subjectively feel drowsy or sleepy. Teenage drivers and their parents have to be advised of this effect. Bowel motility will be affected even after a prolonged administration of opioids, and constipation is a common complaint. Combining opioid therapy with a bowel regimen is advisable. Adolescent patients taking opioids for years may experience delayed puberty because testosterone and estrogen levels can be decreased. Hormonal supplements might be necessary.

**Table 55-3** Dosing Strategies for Frequently Used Sustained-Release Opioid Analgesics

GENERIC NAME	PEDIATRIC DOSE AND FREQUENCY	INITIAL ADULT DOSE RANGE AND FREQUENCY	INDICATIONS	COMMENTS
Morphine—sustained release	No specific pediatric dosing has been established, follow adult dosing	Dose dependent on previous opioid requirement; lowest dose: 15 mg q12h Interval: MS Contin and Oramorph q8–12h	Moderate to severe pain when opioids are needed for a prolonged period	Patient needs to be able to swallow whole pill Fatal overdose possible if chewed
Oxycodone—sustained release	No specific pediatric dosing has been established, follow adult dosing	Dose dependent on previous opioid requirement; lowest dose: 10 mg q12h	Moderate to severe pain when opioids are needed for a prolonged period	Patient needs to be able to swallow whole pill Fatal overdose possible if chewed
Fentanyl transdermal system (Duragesic)	No specific pediatric dosing has been established, follow adult dosing	Dose dependent on previous opioid requirement Lowest dose: 12 mcg/hr Patch needs to be changed q72h	Moderate to severe pain when opioids are needed for a prolonged period	Initial dose should not exceed 25 mcg/hr Unauthorized simultaneous use of multiple patches can lead to fatal overdose

Once patients have received opioids on a regular basis for more than a week to 10 days, they cannot simply stop using these drugs; they need to be weaned off of them. The body has developed a physical tolerance, receptors have changed in response to the long-term administration, and immediate discontinuation of drug therapy would lead to withdrawal symptoms. Decreasing the total dose by 10% every day to every other day is a common approach to weaning opioids, although this area is one of continuing research. For children who have received opioids for weeks or months, this approach might be too aggressive. Weaning just once or twice a week might be more adequate, especially in an outpatient setting where symptoms of withdrawal might be missed. Parents should be informed that signs of withdrawal include subtle ones, such as yawning, lacrimation, rhinorrhea, nasal stuffiness, or insomnia, as well as the more commonly associated, extreme ones of restlessness, chills, tachycardia, hypertension, nausea and vomiting, crampy abdominal pains, and diarrhea. When the parent reports subtle signs of withdrawal, stopping the weaning process for a few days before resuming it at a slower rate is best. More severe signs of withdrawal require a return to a higher dose, stabilization at the higher dose for a few days, and then return to a slower rate of continued weaning.

#### **Controlled Substances, Patient Care, and the Law**

The use of opioids for chronic pain has been controversial. Some authors have argued that opioids should never be used for chronic, nonmalignant pain because their use would only lead to dependency, tolerance, and dose escalations. Clearly, daily use of opioids always results in physical dependence, although not psychological addiction, tolerance, and a potential

need for a higher dose. The use of opioids may be justified when it can be demonstrated that the pain has been reduced and the patient's function has significantly improved. When initiating opioid therapy, the status of the patient should be clearly documented, and therapy should be objectively assessed later. The physician is advised to sign contracts with the families detailing who can write prescriptions for opioids, where these prescriptions can be filled, whom to contact when the prescribed doses are inadequate, and what happens if patients run out of medications early or lose their medications. The individual patient's and the family's risk for abuse and diversion of medications needs to be reviewed carefully. State medical boards and the US Drug Enforcement Administration provide further information on their respective Web sites.

#### **Adjuvant Analgesics**

Adjuvant analgesics are most commonly used in the treatment of chronic neuropathic pain. Few randomized controlled studies have examined the efficacy of these analgesics in chronic pain management, although they have been used for at least 20 years. Experiences in adults have been extrapolated to administration in children because no comparable studies in children have been conducted. Physicians accustomed to the efficacy of NSAIDs or opioids in acute pain management are often surprised by how little and varied improvement these medications seem to provide (for every 100 patients taking antidepressants for chronic pain, only 30 experience at least a 50% reduction in pain).

In adult patients, there are FDA indications for several medications for particular pain syndromes, such as postherpetic neuralgia, diabetic peripheral neuropathy, and fibromyalgia. None of the adjuvant analgesics

has specifically been approved for the treatment of chronic pain in children. Thus all current use remains off label. The child and the family need to be advised that treatment often involves trial and error. Gradual titration to effect is recommended to limit early adverse effects on orthostasis or cognition, effects that may resolve with time.

**ANTICONVULSANTS.** Anticonvulsants suppress neural hyperexcitability, which might explain their effectiveness in chronic pain management. Gabapentin has been indicated for the adjunctive treatment of partial seizures in children as young as 3 years. Therefore, the experience in children with this particular drug is more extensive than with others in this class. Gabapentin is a widely used adjunctive analgesic in children and is usually well tolerated. The most common adverse effects are dizziness, somnolence, ataxia, fatigue, and weight gain. Weight gain can be particularly concerning in the treatment of lower extremity pain because it may complicate the rehabilitation process. Therapy is usually initiated on a once-a-day basis and advanced up to 3 doses per day if necessary. Doses can be increased every 2 to 5 days. Many physicians begin with nighttime dosing and also increase the nighttime dose first so that potential sedation and dizziness may be less apparent. If patients experience an improvement in pain relief, doses can be raised as long as no significant adverse effects occur. The patient and family should be told that these medications do not work immediately; a week might pass before patients note any improvement at all. Pregabalin is currently indicated for treatment of pain caused by diabetic peripheral neuropathy, postherpetic neuralgia, and fibromyalgia in adults, but it is commonly used off label for other neuropathic pain disorders. Experience in children continues to be limited. It remains to be seen whether initial reports of pregabalin treatment of dysautonomic crisis can be extended to an amelioration of autonomic symptoms commonly associated with painful congenital connective tissue disorders. Adverse effects and toxicity have limited the use of other anticonvulsants. Lamotrigine has been associated with Stevens-Johnson syndrome, tiagabine with seizures, and topiramate with hyperthermia. Older anticonvulsants such as phenytoin, carbamazepine, and valproate require periodic monitoring for potential end-organ toxic effects.

**ANTIDEPRESSANTS.** Evidence of the efficacy of antidepressants in chronic pain management has been best for agents that have a local anesthetic-like effect on neural sodium channels and interfere with the reuptake of norepinephrine. These drugs include TCAs such as nortriptyline and amitriptyline and SNRIs such as duloxetine and milnacipran. SSRIs seem to be less effective but are helpful when associated depression, sleep disturbance, and anxiety are present.

All antidepressant drugs carry an FDA-required boxed warning label alerting health care providers to an increased risk for suicidality (suicidal thinking and behavior) in children and adolescents being treated with these agents. When initiating antidepressant therapy, the FDA advises health care providers to evaluate children and adolescents every week for the first 4 weeks, then every other week for the next 4 weeks, and again at 12 weeks to assess for potential mood changes.

Other side effects of TCAs include dry mouth, constipation, urinary retention, sedation, and cardiovascular effects such as hypotension and disturbances of conduction. Rare reports have surfaced of sudden death associated with TCA therapy. A baseline electrocardiogram should be obtained to identify children with a pre-existing conduction defect. The side-effect profile varies between the drugs: Nortriptyline has fewer anticholinergic side effects than amitriptyline, whereas amitriptyline is the more sedating. Sedation can be turned into a therapeutic advantage when treating patients who complain of nighttime awakenings caused by pain. Patients should be advised to avoid high-calorie drinks to relieve the sensation of dry mouth because they can contribute to undesirable weight gain.

As is the case with anticonvulsants, pain relief is delayed and cannot be expected for at least a week or more. No established correlation exists between plasma concentration of TCAs and analgesic efficacy. Routine measurement of plasma drug levels is rarely indicated. If use of the drug needs to be discontinued, then the dosing should be tapered over a few weeks to avoid irritability and agitation.

**MEMBRANE STABILIZERS.** Membrane stabilizers are drugs that interfere with the ionic fluxes required for initiation and conduction in peripheral and central neurons. These medications are available in a variety of applications: intravenous lidocaine, oral mexiletine, and transdermal lidocaine patches. All of these drugs are thought to be particularly helpful in the treatment of neuropathic pain. Intravenous lidocaine and oral mexiletine are second-line therapy usually reserved for patients who show insufficient improvement after therapy with other adjuvants such as anticonvulsants or antidepressants. Adverse effects include nausea, vomiting, sedation, and ataxia, which limit the usefulness of membrane stabilizers. Initiation of this therapy will most frequently occur after consultation with a pediatric pain specialist; however, the application of transdermal lidocaine might be considered by the pediatrician. As with many therapies, these patches have not been specifically evaluated in children. Their indication, at this point, is solely for postherpetic neuralgia, but they are useful in a variety of other localized neuropathic pain conditions associated with allodynia and hyperesthesia. The patches are applied to the area for 12 continuous hours a day. Cutting patches to size and gradually moving two cut strips from the periphery to the center of a hyperesthetic area may permit therapy in patients who initially cannot tolerate the direct application of a patch in a sensitive area. Adverse effects are usually limited to local irritation because the systemic absorption of lidocaine through intact skin is low. Parents should be warned, however, to keep the patches out of reach of small children because overdose can occur when the patches are chewed or swallowed. At least 95% or 665 mg of lidocaine will still be present in the patch after 12 hours of application.

**ALPHA AGONISTS.** Drugs such as clonidine are centrally and peripherally sympathoplegic. They stimulate  $\alpha$ -adrenoreceptors in the brainstem, resulting in reduced sympathetic outflow from the central nervous system, and they stimulate prejunctional receptors on peripheral

neurons, reducing norepinephrine release. Epidural use of clonidine has been found to be effective for neuropathic pain syndromes. Transdermal clonidine prophylaxis has also been evaluated as an adjunct, preventing withdrawal symptoms in children who were sedated in the intensive care units for a prolonged period. Adverse effects may include sedation, bradycardia, and hypotension. A list of the most frequently used adjuvant analgesics can be found in Table 55-4.

### Interventional Therapy

If the patient's condition rapidly deteriorates or does not improve after a period of several weeks despite a

multidisciplinary approach, including psychological and pharmacologic interventions and physical therapy, the pain specialist might consider a regional anesthetic. A regional anesthetic may be particularly helpful if the painful condition is limited to a single extremity, as is often the case in CRPS type 1. Interventional therapy extends from the injection of a single peripheral nerve with local anesthetics and steroids, to a more extensive intravenous regional or sympathetic nervous system block of an extremity, and finally to a hemi-body neuraxial block through an epidural injection. Most young children will require sedation for these procedures; thus, pediatricians

**Table 55-4** Dosing Strategies for Frequently Used Adjuvant Analgesics

GENERIC NAME	PEDIATRIC DOSE AND FREQUENCY	INITIAL ADULT DOSE RANGE AND FREQUENCY	INDICATIONS	COMMENTS
Gabapentin	5–60 mg/kg divided into 2–3 daily doses Start at 5 mg/kg for <20 kg, 100 mg for <50 kg, 300 mg for >50 kg Titrate q1–3d as needed	300 mg Titrate 300 mg/day q1–3d, up to 3,600 mg divided 3 times daily	Postherpetic neuralgia Neuropathic pain, migraine prophylaxis	CNS effects (somnolence, dizziness, etc) Do not stop abruptly—risk for seizure in susceptible patients
Pregabalin	No specific pediatric dosing established	50 mg; 50 mg tid or 75 mg bid Titrate up to 300 mg/day in 1 wk as needed	Postherpetic neuralgia, diabetic peripheral neuropathic pain, neuropathic pain, fibromyalgia	CNS effects (somnolence, dizziness, etc) Do not stop abruptly—risk for seizure in susceptible patients Discontinuation syndrome
Topiramate	No specific pediatric dosing established	25 mg Titrate to 50 mg q12h in 4 wks as needed	Migraine prophylaxis	Risk for metabolic acidosis, oligohidrosis, hyperthermia
Amitriptyline Nortriptyline	10–25 mg qhs Titrate up to 2–3 mg/kg (max. 150 mg), qhs or twice-daily dosing	25–50 mg qhs Titrate up to 150 mg/day	Neuropathic pain, chronic pain	Sedation, anticholinergic, and cardiac effects, ECG recommended before initiation of therapy
Paroxetine	No specific pediatric dosing established	20–60 mg/day	Diabetic peripheral neuropathic pain, fibromyalgia, chronic musculoskeletal pain	Hepatic toxicity, discontinuation syndrome
Doxepin	12.5 mg/kg qhs Titrate up to 100 mg/day in 1–3 doses	75 mg, divided in 1–3 doses Titrate up to 150 mg/day	Neuropathic pain, chronic pain	Do not use in children <12 years of age
Trazodone	No specific pediatric dosing established	50 mg qhs Titrate up to 200 mg qhs or 400 mg/day in divided doses	Chronic pain	Risk of priapism—avoid in male patients

CNS, central nervous system.

should refer the patient to a pain management facility that is capable of providing this kind of care.

### **Intravenous Regional Block (Bier Block)**

Intravenous regional anesthesia is indicated for painful conditions of the arm below the elbow or the leg below the knee. An intravenous cannula is inserted in a distal vein in the limb, and a tourniquet is applied to the upper arm or thigh. Before inflation of the tourniquet, the limb may be exsanguinated (blood removed) by wrapping the distal part of the limb with an elastic bandage. This procedure can increase the efficacy of the block but may be poorly tolerated in patients with chronic pain. Local anesthetic and ketorolac infusion have been found to be efficacious in some children with CRPS type 1. Complications, although rare, can occur if the tourniquet suddenly deflates soon after the local anesthetic has been injected. The sudden increase in serum level of the local anesthetic will lead to the well-known neurologic adverse effect of an overdose: dizziness, tinnitus, loss of consciousness, and convulsions. Serious cardiac adverse effects are rare but can occur if bupivacaine is the local anesthetic or if convulsions are inadequately treated.

### **Sympathetic Blocks**

Sympathetic blocks are injections of local anesthetic into a particular area of the ganglionic chain of the sympathetic nervous system: at the stellate ganglion for the upper extremity and at the lumbar sympathetic plexus for the lower extremity. The pain specialist may use ultrasound, fluoroscopy, or computed tomography for guidance in the placement of the block. Indications for this intervention are chronic pain syndromes such as CRPS type 1, in which the sympathetic nervous system may contribute to the painful condition. After the block, the patient experiences a warming in the extremity, and the physician can register a measurable increase in temperature in the extremity, which helps in assessing the efficacy of the block in multiple ways. If temperature is increased and the patient reports pain relief, then the pain is considered as sympathetically maintained. If the pain relief lasts beyond the expected duration of the local anesthetic block, then the injection will be considered not only diagnostic but also therapeutic. Depending on the duration of pain relief, the block can be repeated. Repeated injections might provide progressively longer periods of pain relief. If the injection resulted in an increase in temperature, but no improvement in pain occurred, then the condition has to be considered sympathetically independent. Repeating the block has no benefit. If the injection did not result in a temperature change in the extremity the block was technically inadequate. Even in this condition, the patient might report an improvement in pain, a so-called placebo response, a situation the specialist will have to contemplate when deciding on further interventions. Lumbar sympathetic blocks in children with CRPS can lead to measurable reductions in allodynia, although the individual response varies with almost as many patients reporting increases in overall pain scores as decreases.

Adverse effects of sympathetic blockade include typical findings of Horner syndrome in case of a

stellate ganglion block: drooping of the eyelid, conjunctival injection, and stuffy nose on the injected side. Hoarseness can also occur. These effects will persist only for the duration of action of the injected local anesthetic. Other adverse effects include local anesthetic overdose after unintentional intravascular injection or injury to adjoining structures such as a pneumothorax. If a sympathetic nerve block has repeatedly provided good analgesia but was of insufficient duration, then a surgical sympathectomy may be considered.

### **Implanted Devices**

In children, therapeutic interventions will only occasionally progress to the invasiveness of an implanted device. Pediatricians are already familiar with these forms of therapy as an advanced mode in the management of spasticity in a child with cerebral palsy. An intrathecal catheter is surgically implanted at the lumbar level of the spinal cord. It is then tunneled to a reservoir device, which is usually placed in a subcutaneous pocket in the lower abdomen. The reservoir can be filled with local anesthetic, opioids, and clonidine. Because the drugs are delivered directly into the spinal fluid, drug doses can be much smaller than is the case with enteral or parenteral delivery. Patients have to return to the pain management center every 4 to 8 weeks for a refill. The device is programmable through telemetry. Program modes can range from a simple continuous infusion to more complex modes with additional boluses at particular times of the day when increased pain-associated activities are anticipated.

In the case of spinal cord stimulation, electrodes are surgically placed in the epidural space by a minimally invasive approach and connected to an implanted controller. A similar device is used for peripheral nerve stimulation, with electrodes positioned in the direct vicinity of a nerve such as the occipital nerve. Multiple parameters of the repetitive electrical impulses such as duration, intensity, and pulse width can be manipulated. Patient cooperation during implantation is paramount to achieve an optimal result. Therefore, this device is reserved for the occasional older adolescent with severe, unrelenting pain. Discussions of adverse effects for these therapies have to include not only possible immediate surgical complications but also the need for long-term maintenance.

### **Referral to a Pediatric Pain Specialist**

Patients with complex disease processes and significant disability and impairment in function will challenge the pediatrician. Patients who have uncontrolled pain or loss of function despite therapy, significant comorbid diseases, a need for more invasive testing or treatment, or a family who are looking for another opinion should be referred to a pain specialist. The pediatrician has 2 options in this case: either remain the primary coordinator of the multimodal treatment team with the pain specialist as one of the providers, or allow the pain specialist to become the coordinator of the team. Which option is optimum will depend not only on the complexity of the patient's problem but also on the distance the family will have to travel to see the specialist. A listing of pediatric pain treatment centers available from the American Pain Society

reveals that many families need to cross state lines to obtain this kind of care for their child. Ideally, the pediatrician, who is familiar with the patient, the family, and the local resources, will work in close consultation with the pain specialist.

### Discontinuing Treatment

Periodically, all treatment modalities should be assessed to see whether they are still effective or even necessary. A change in function may no longer be dependent on a particular therapy because the overall physical status of the patient has improved. Discontinuing therapy can be a challenge because many patients and families fear that the painful condition will recur. A gradual weaning of therapy is an option even when no clear pharmacologic necessity exists.

Patients who require long-term management of their pain and coordination of multidisciplinary therapies beyond their adolescent years will benefit from a planned, gradual, and collaborative approach to the transition of care. Many of these patients have underlying processes such as congenital diseases, neuromuscular impairments, or post-traumatic conditions.

### Palliative Care

Insufficient relief of pain is one of the most common patient complaints in the management of progressive cancer or other life-threatening/life-limiting illnesses. All therapeutic interventions that have been discussed in this chapter should be considered in the management of a patient with a potentially life-threatening disease. Waiting until the child has only days to live to consider more invasive therapy will lead to needless, avoidable suffering. Components of palliative care should be offered at diagnosis and throughout a potentially life-threatening disease. For placement of an implantable device, the child should have a life expectancy of 3 to 6 months. If the life expectancy is less than 3 months, then a tunneled catheter connected to a conventional infusion pump or a PCA device is an option. Neurolytic blocks can provide the patient and family with valuable pain-free or painless time.

### CONCLUSION

The prevalence and significance of chronic pain in children and adolescents have only recently been recognized. Chronic pain can limit the functional abilities of the child, prevent normal age-appropriate development, and have a significant impact on other members of the family. A multidisciplinary approach is preferred when assessing the patient and providing therapy. A team comprising the pediatrician, who has an established rapport with the family, and specialists, such as a physical therapist, psychologist, and pain management consultant, may be most effective in providing care even for the challenging patient.

## Chapter 56

# SELF-REGULATION THERAPIES: HYPNOSIS AND BIOFEEDBACK

Denise Bothe, MD; Karen Olness, MD

Children learn self-hypnosis easily and can apply it to help solve problems such as acute and chronic pain, undesirable habits, anxiety associated with chronic illnesses such as hemophilia or cancer, performance anxiety, and enuresis. Self-regulation techniques can also be used to help children manage everyday life stressors better. Training in hypnosis has been used for many years by athletes and other performers. The teaching and application of self-hypnosis is enhanced by the addition of biofeedback, which provides proof to the child that changes in thinking result in changes in body responses. Children, adolescents, and their families can gain an increased sense of control and participation in their treatment by learning effective coping strategies such as those available through self-hypnosis, with or without biofeedback.

### HISTORY

Hypnosis techniques have been used since the late 18th century. The Franklin Commission, which investigated the claims of Franz Mesmer, included experiments involving children. In the 1840s, two British surgeons, John Elliotson and James Braid, both reported surgical procedures on children during which hypnosis was the sole anesthesia method. In the late 19th century, European clinicians reported successfully treating negative habits and pain in children with hypnosis. The first research studies in children using hypnosis were in the 1960s and assessed hypnotizability. Since then, researchers have recognized that children generally learn hypnosis more

quickly and easily than do adults. The first use of biofeedback with children was reported in the 1970s, and since the 1970s, increasing research has documented the ability of children to use hypnosis, with or without biofeedback, to treat many clinical conditions.

Three-day training workshops on hypnosis with children were first taught in 1976 and have been available annually since then.

## DEFINITIONS

*Hypnosis* is defined as a focused state of awareness, sometimes involving relaxation, during which the individual has enhanced ability to facilitate specific physiologic and behavioral outcomes. *Hypnotherapy* is defined as a treatment modality that uses hypnosis by integrating that focused state of awareness into treatment.

Many terms have been used to describe the process of hypnosis (Box 56-1). *Mesmerism* was the original term used to describe the clinical work of Franz Mesmer. James Braid, an English surgeon, first coined the term *hypnosis*. This designation was unfortunate because *hypnos* came from the Latin root for sleep, implying that the person in hypnosis is asleep. However, this is not the case, and hypnosis remains misunderstood. Since then, many other terms (see Box 56-1) such as *self-regulation* and *mind-body skills training* have been used. *Cyberphysiology* is another term coined in the 1980s to describe these same techniques. The prefix *cyber* is derived from the Greek *kybernan*, which means to steer or take the helm; thus cyberphysiology refers to a person's ability to steer or regulate a physiologic or behavioral response.

Some of the more common misconceptions about hypnosis include the following:

- Hypnotists exert mind control over passive subjects.
- Hypnosis is magic.
- When under hypnosis the subject is sleeping.
- Only a few people are able to be hypnotized.

None of these statements is true. The subject is fully awake during hypnosis and aware of the environment. The mind and mental imagery of the person using these mind-body skills causes the physiologic changes. Although some people find these skills easier to acquire than other people, anyone can learn self-hypnosis.

*Biofeedback* is a term coined in 1969 to describe the procedure of using a physiologic response measure, or signal from the body, to give feedback to the

person. This feedback increases the awareness of the body and how it is functioning. Biofeedback is a useful tool in training individuals to strengthen their mind-body connection and learn self-regulation skills. Although biofeedback is a useful adjunct, training in biofeedback requires self-hypnosis instructions, which lead to the desired physiologic changes.

Measures of physiologic response include skin temperature, galvanic skin resistance (GSR) or electrodermal activity, electroencephalographic (EEG) data, breathing, heart rate, and heart-rate variability. Simple skin-temperature monitors make an inexpensive and effective biofeedback tool. Nocturnal enuresis alarms are essentially biofeedback tools.

Another biofeedback computer program that was originally designed for adults and has also been successful with children is the emWave (formerly Freeze Framer) program ([www.heartmath.com](http://www.heartmath.com)) (Figure 56-1). A finger sensor connected to the computer measures the heart-rate variability. As the person relaxes, the image on the computer screen gives positive feedback. For example, a rainbow comes down and fills a pot with coins, and in another a hot-air balloon floats up and across a field as the player relaxes. This program calculates heart rate variability and shows the patient and practitioner how well the patient was able to relax. The program has a graphical representation that shows the details of the session with heart-rate variability over time and percentage of time during which the subject was at low, medium, and high levels of relaxation. Feedback can then be compared with the data from other sessions from the same subject to determine progress. Heartmath also makes a portable emWave personal stress reliever biofeedback device.

## COMMON GROUND

Health professionals use many terms such as *imagery*, *relaxation imagery*, *progressive relaxation*, and *meditation*, among others, all of which refer to the same process by which hypnosis is induced. Although

### BOX 56-1 Terms Used to Describe Self-Regulation Techniques Involving Hypnosis

- |                             |                          |
|-----------------------------|--------------------------|
| • Self-hypnosis             | • Relaxation             |
| • Mind-body skills training | • Progressive relaxation |
| • Self-regulation           | • Meditation             |
| • Biofeedback               | • Visual imagery         |
| • Diaphragmatic breathing   | • Guided imagery         |
|                             | • Cyberphysiology        |

**Figure 56-1** Biofeedback program measures heart rate variability through a finger sensor connected to the child's finger.

great confusion and disagreement exist in the definitions of the variety of terms used, common ground can be found among terms. For example, hypnosis often uses relaxation and imagery techniques, and biofeedback can be used to augment a person's body-physiologic awareness during hypnosis. In addition, imagery and relaxation techniques, which are hypnosis methods, are used in biofeedback to help increase the person's focus and awareness. Culbert and colleagues describe the biofeedback-hypnosis interface and the rationale for integrating these self-regulation or cyberphysiologic techniques with children and adolescents. These skills all foster empowerment, mastery, and self-control. Many athletes use these skills to improve performance, and many patients use them to improve their health and body functions.

## GUIDELINES FOR LEARNING AND TEACHING SELF-HYPNOSIS

Before training a child in self-regulation skills, the pediatrician or other child health professional should prepare the child and family (Box 56-2). The choice of strategies for teaching self-hypnosis to children varies, depending on the child's age and developmental stage, the preferred type of mental imagery (ie, visual, auditory, kinesthetic, olfactory), learning style, preferred activities, dislikes, and personality. The pediatrician who provides coaching or teaching of hypnosis should emphasize that the child is in control and can choose when and where to use self-hypnosis. The pediatrician should be knowledgeable about the basic problem of the child before embarking on a hypnotherapeutic intervention. For example, a general pediatrician should be able to assess whether all necessary diagnostic tests have been completed for the presenting problems of abdominal pain, headache, or enuresis before offering training in self-hypnosis. A general pediatrician would not teach self-hypnosis to a child with posttraumatic

stress disorder (PTSD) unless working closely with a child psychiatrist or psychologist who was experienced in assessment and treatment of PTSD.

Training in self-hypnosis is helpful to a pediatrician or other clinician interested in using these skills to help children. Much can be learned about the language used to promote mind-body control and self-confidence in a child. The language used should be permissive, allowing the child to feel a sense of control. However, many techniques that use mind-body or hypnosis methods can be used in a primary care setting without formal training. Understanding a child's needs, increasing the child's understanding of mind-body control, and helping the child feel comfortable will promote a sense of control and increase the child's ability to regulate her or his body and behavior. Techniques that help a child focus and relax may be taught as part of hypnosis (Box 56-3). Deep breathing, often called *diaphragmatic breathing*, or *belly breathing*, is a powerful way to focus the child's attention and start the relaxation process. Progressive muscle relaxation is useful for older children who understand the instructions. Young children may respond better to *becoming floppy* as they relax. Leora Kuttner has described strategies for working with preschool children in pediatric practice.

Imagery techniques work best when the clinician has an understanding of the child's developmental stage, likes, dislikes, and fears. The clinician should help each child choose relaxation and imagery methods that suits him or her. It is recommended that a child practice 10 to 20 minutes twice daily for 1 month then once daily for the second month. Because biofeedback and hypnosis are designed to promote self-control, the parents should not remind their child to practice; children should develop their own reminder system (eg, a ribbon around the neck of a favorite stuffed animal). Adding a biofeedback measure (eg, to monitor pulse and heart rate variability, peripheral temperature, or GSR) may help the child improve. An audio recording may also be an effective reinforcer.

### BOX 56-2 When Teaching a Child Self-Regulation Techniques

1. Conduct a thorough diagnostic evaluation to understand the effects of the problem on the child and the significance of symptoms for the family.
2. Understand the child by learning about the child's personality, interests, likes, dislikes, and developmental stage, and any learning disabilities.
3. Emphasize the need for practice by explaining that becoming proficient in self-hypnosis requires practice, similar to learning, for example, a sport or music skill.
4. Emphasize that the child, not the parent, is the client; thus parents should be supportive but should not remind their child to practice.
5. Throughout the process, emphasize the child's control because the *child being in control* is the principal key to success.

Derived from Kohen DP, Olness KN. Self-regulation therapy: helping children help themselves. *Ambul Child Health*. 1996;2:43-58.

## CLINICAL APPLICATIONS

Mind-body interventions constitute a major portion of the overall use of complementary and integrative medicine by the public. National survey data published in 2004 showed that five relaxation techniques along with imagery, biofeedback, and hypnosis, taken together, were used by more than 30% of the adult US population.

### BOX 56-3 Techniques to Help a Child Focus and Relax

- Deep breathing
- Relaxation (eg, progressive muscle relaxation)
- Mental imagery
- Guided imagery
- Therapeutic suggestions
- Adjunct biofeedback

### BOX 56-4 Clinical Applications of Child Hypnosis

- Pain:
  - Acute (eg, injury, illness, procedural)
  - Chronic or recurrent (eg, chronic illness, disability, trauma, recurrent procedures)
- Habit problems and disorders (eg, thumb sucking, nail biting, hair pulling [trichotillomania], habitual coughs, tics)
- Behavioral problems (eg, attention problems, anger management)
- Medical-biobehavioral disorders (eg, asthma, migraine, Tourette syndrome, inflammatory bowel disease, warts, pruritus)
- Anxiety (eg, performance [examinations, stage fright, sports], anxiety disorders, PTSD, phobias)
- Psychophysiologic problems (eg, enuresis, encopresis, conditioned nausea and vomiting, irritable bowel syndrome, sleep disorders)
- Chronic disease, multisystem disease, terminal illness (eg, cancer, hemophilia, AIDS, cystic fibrosis, diabetes, chronic renal disease)

Derived from Kohen DP, Olness KN. Self-regulation therapy: helping children help themselves. *Ambul Child Health*. 1996;2:43-58.

Hypnosis and biofeedback are generally categorized in the mind-body aspects of complementary and integrative medicine; however, increasingly, medical institutions are considering hypnosis and biofeedback as part of mainstream medicine. Pediatricians and other health care professionals see many children who exhibit symptoms of high stress levels, including such symptoms as anxiety, depression, headaches, abdominal pain, and school avoidance. Children and parents often feel out of control, with busy lives, worries, or chronic health problems. Children and adolescents may attempt to cope in self-injurious ways, such as with the use of alcohol, nicotine, and drugs.

A thorough medical evaluation should precede hypnosis, with or without biofeedback treatment. Children referred for integrative treatment may not have had adequate diagnostic evaluations. In a study that reviewed 200 cases of children referred specifically for treatment with hypnosis, biofeedback, or both, 25% of the children had unrecognized biologic bases for symptoms such as enuresis, headache, anxiety, and recurrent abdominal pain. Some of the children referred for hypnosis to control headaches proved to have sinusitis, food allergies, brain tumor, or carbon monoxide poisoning.

Children have been taught self-hypnosis for a wide range of problems (Box 56-4). The mind-body skills learned with hypnosis can give a child the capacity to change attitudes, emotions, behavior, habits, autonomic reactivity, and biologic functions. This self-regulation offers techniques that facilitate their ability to:

- Direct their behavior
- Modulate physiologic changes in desired directions
- Control their thoughts for the purpose of symptom control

- Attain and maintain health and wellness
- Improve function or enhance performance

## PAIN MANAGEMENT

Pain is a subjective experience, and children exhibit different tolerance levels. Hypnosis techniques can be used for pain control, for example, in emergency rooms or for children with cancer who are undergoing procedures. When in acute pain, children are in a more focused state of awareness and are highly motivated to feel better. Because of this motivation, they may be more likely to respond to suggestions that increase their sense of control, which they can then use to decrease their sensation of pain. Helping children *dissociate* by imagining that they are in a favorite place can have a calming effect. In some situations, such as a first-time migraine headache, it can be difficult to work with a child who is acutely miserable. While not always possible, it is preferable overall to teach children these techniques when they are well, allowing them to prepare themselves for the possible acute episode. Some of these effective self-regulatory techniques are described in the literature. A book by Kuttner offers guidance for health professionals to help children in pain using self-regulation techniques.

Chronic pain and recurrent pain are more difficult to manage than acute pain. A child who experiences pain over a long period or learns to expect the pain to return again and again may become increasingly anxious and develop feelings of hopelessness. Teaching self-regulation is more complicated in these situations because of the need to address the severity and the negative expectancy that accompanies chronic pain. It has been shown that children will benefit more and require less training if they are offered training very early, ideally within a few days, after diagnosis of a chronic or life-threatening disease. *No Fears, No Tears* and *No Fears, No Tears—13 Years Later* are 2 video productions that illustrate the use of self-regulation strategies with children who have cancer.

If the self-regulatory techniques seem ineffective for the child with chronic or recurrent pain, then the pediatrician should re-evaluate the situation. The pain may be serving a protective psychological purpose. Significant mental health issues, such as PTSD, depression, or abuse, may exist, and psychotherapeutic evaluation and intervention may be needed. (See Case Report, Box 56-5.)

## HABIT DISORDERS

Habit problems are common in children. Habit problems such as thumb sucking, nail biting, hair pulling (trichotillomania), or habitual cough are potentially responsive to hypnotherapy. In a retrospective study, a significant number of children with habitual cough responded well to hypnosis with resolution of their symptoms of cough.

Some types of habits, such as tics or hair pulling, often begin during a stressful experience and initially carry with them emotional significance. In most instances, the emotional significance disappears, yet the habit remains. Habits such as habitual cough may begin with an upper respiratory tract infection but

**BOX 56-5 Case Report—Abdominal Pain**

Sarah, a 6-year-old girl, was brought to the pediatrician by her mother because of severe abdominal pain of 2 months' duration. The pains started suddenly one day in the morning after breakfast and before school. They occurred many mornings of the week and lasted for 1 to 2 hours. Sarah would clutch her abdomen and double over with pain. She did not have vomiting or diarrhea or fever. After the pain resolved, each day she appeared healthy. She had no history of constipation. Medical workup was negative for any medical causes of her pain.

A complete history revealed that Sarah did not want to go to school. She was afraid because a classmate on her school bus was saying things to scare her. The abdominal pain kept her home and protected her from the child who was scaring her.

Sarah's pediatrician spoke with her mother about addressing this issue with school officials and then asked Sarah if she wanted to learn a way to help herself prevent the pain from arising and decrease the intensity when it did occur. Sarah was interested. She liked dolls and stuffed animals; thus she was asked if she had one that was very soft and squishy, and she did. Sarah was taught to take slow, deep breaths "into her belly," and then advised to "make her belly very soft" like her squishy stuffed animal. This exercise would help her belly work better and prevent the pain from coming. Sarah demonstrated in the office that she was able to perform this task. She was then advised to practice this deep breathing and making her belly soft at home. (This teaching took approximately 5 minutes of the office visit.)

One month later, Sarah's mother brought her back for a well-child check. Sarah had had only one more episode of abdominal pain after learning how to relax herself and her abdomen. She has not had similar recurrent abdominal pains since. Sarah's mother also addressed the issue of the child who was scaring Sarah by talking to the principal, teacher, and bus driver. Sarah now enjoys going to school and does well with her friends and schoolwork.

persist long after the infection is gone. Others, such as thumb sucking, may have begun as a comfort measure in young childhood and have become habitual. Unless a motivation exists behind the habit (eg, if the habit helps the child avoid school), and provided that the child is motivated to change (not just the parent), hypnosis techniques are effective in extinguishing the habit. Emphasizing the child's control in mastering the problem is crucial to success in eliminating the problem.

**ENURESIS**

Before considering hypnotherapy for enuresis, the pediatrician should distinguish whether the enuresis is primary or secondary and whether the enuresis occurs during both day and night or at night only (see Chapter 249, Enuresis). Organic causes such as urinary tract infection, diabetes, and constipation must be ruled out. Primary enuresis may be considered a maturational issue, whereas secondary enuresis, after

a period of dryness, may be associated with a significant stressor in the child's life. Enuresis that has no organic cause is expected to resolve spontaneously over time. Depending on the age of the child, enuresis can be quite frustrating and interfere with activities such as sleepovers. Children with nocturnal enuresis often feel shame or guilt. Various methods have been used for children and parents who wish to stop enuresis; these include motivational behavior management (including reward systems, the child helping in cleanup of the wet bed, and bedwetting alarms) and medications such as desmopressin. Hypnotherapy is helpful for many children with enuresis. In a study that compared two groups of children treated with hypnotherapy versus imipramine, comparable results were seen with each group. At long-term follow-up, the group treated with hypnotherapy had a significantly larger positive response. Drugs such as imipramine can have significant side effects and can be life threatening. Desmopressin has negligible known side effects, but some parents are reluctant to give their child medication. The bed-wetting alarm is a type of conditioning device and is quite effective, although some children find the alarm to be aversive. Hypnosis as a treatment is at least as effective, has longer duration, and is not life threatening. As a treatment option for enuresis, self-regulation therapy or hypnosis is the least invasive, and many children respond favorably.

**BEHAVIORAL AND ATTENTION DISORDERS**

Self-regulation has value as an adjunct in management of behavioral problems. In addition to therapeutic interventions, such as counseling and behavioral modification, teaching self-regulation techniques to a child can be a constructive way to build self-esteem and more effectively control the maladaptive behaviors. Attention-deficit/hyperactivity disorder (ADHD) is one of the most common behavioral problems encountered in children. Recommended management usually involves behavioral modification and primarily stimulant medication. A review of research studies that use neurofeedback for ADHD shows potential for short- and long-term improvement from ADHD symptoms. One study using biofeedback and hypnosis techniques has demonstrated beneficial effects of EEG biofeedback on measures of intelligence, behavioral rating scales assessing the frequency of core symptoms of ADHD, computerized tests of attention (eg, the Test of Variables of Attention [TOVA]), and quantitative EEG measures of cortical arousal. Evidence is promising for neurofeedback as a treatment alternative for ADHD, but more research needs to be done to be certain about efficacy for neurofeedback.

**STRESS MANAGEMENT AND ANXIETY**

Self-regulation skills are an excellent way to manage stress. Relaxation and hypnosis are useful for helping children and adolescents with symptoms of anxiety. Many parents bring children to their pediatricians for symptoms related to high stress levels. Stress and anxiety can manifest in a variety of ways, including

**BOX 56-6 Case Report—Anxiety**

Dan, age 16, was referred to learn self-hypnosis for control of test anxiety. He had been an excellent student during all his school years until a year earlier, when he began to perform poorly on examinations. No changes occurred in his studying habits. He did very well on homework. No family changes had occurred. He got along well with two older siblings, both of whom are now in college. Dan had a girlfriend, a classmate, who was also a good student and was looking forward to college.

Dan's mother described him as having always been "perfectionistic." She said that he began expressing worry about examinations when his older brother was taking student aptitude tests. Dan said that he studied and felt that he knew the material but that he froze during the examinations and was unable to think clearly. He also said that he slept poorly on nights before examinations.

Dan said that he enjoyed reading, drawing, playing computer games, swimming, and soccer. He said that his dream was to become an architect. He said that he had been afraid of dogs when a young child but this was no longer so. Dan also said he got approximately 6 hours of sleep on school nights and slept 10 to 12 hours a night on weekends.

The pediatrician explained to Dan that she was able to teach him self-hypnosis to reduce test anxiety and

that his daily practice would be required. She described the use of self-hypnosis by Olympic athletes and the type of practice that was required. The pediatrician emphasized that Dan's parents were not allowed to remind him to practice. Dan said that he wished to learn and was willing to practice.

The pediatrician taught Dan a self-hypnosis method involving progressive relaxation and focus on a winning soccer game. She asked that he practice this method twice daily and return in a week. When Dan returned, he said he had been practicing regularly. At this visit, Dan was hooked to a temperature sensor and was able to watch a screen that demonstrated the increase in his peripheral temperature as he relaxed and achieved self-hypnosis. The pediatrician then taught him specific suggestions to use before his examinations, including suggestions related to sleeping well, and to include future programming of pleasant events associated with successful examinations.

Dan continued to practice daily and was followed up by telephone every 2 weeks for 2 months. At that time, Dan had no further test anxiety, was achieving high scores on tests, and had good grades.

somatic complaints, behavior issues, and poor sleep. Helping children learn self-hypnosis can give them a coping skill they can use anywhere and anytime. When learned at a young age, these stress-management skills can be used for a lifetime to help with daily or extraordinary stressors. Culbert and Kajander have written a book that includes a kit to help children manage stress, sleep problems, and pain. (See Case Report, Box 56-6.)

With children who have an anxiety disorder, such as general anxiety, separation anxiety, or selective mutism, hypnosis techniques can be a useful adjunct along with therapeutic counseling.

**MEDICAL PROBLEMS**

Some diseases respond well to self-regulation techniques. One group of diseases can be classified as *biobehavioral disorders* in that they have clear pathophysiologic origins as well as significant psychoemotional components. Examples of these conditions include asthma, migraine, and irritable bowel syndrome. Relaxation and self-hypnosis help promote a sense of self-control and a reduction of symptoms in children with biobehavioral disorders.

Children and adolescents with asthma can learn self-hypnosis to reduce wheezing in acute episodes. Research using hypnosis, both with and without biofeedback, has demonstrated decreased functional morbidity, with fewer emergency department visits, fewer missed school days, and a better sense of control in children who were taught to use these techniques.

Children with migraine headaches have been shown to respond well, with a significant decrease in frequency of their headaches after self-regulation training when compared to propranolol and placebo. (See Box 56-7.)

Warts are another common condition seen in primary-care pediatrics. Warts are reported to respond to many interventions and often resolve by themselves. In many instances, children will undergo numerous topical treatments without success or with recurrence. Many case studies of successful wart treatment using hypnotherapy have been conducted. (See Box 56-8.)

**DIABETES**

A child with diabetes must cope with frequent blood tests, a special diet, and daily injections. When a child with diabetes feels out of control, compliance with diet and medicines can prove inadequate. Hypnotherapy can provide a child with a way to learn to cope and gain a sense of mastery, both of which may help reduce anxiety and improve compliance.

**MEDICAL PROCEDURES**

Medical procedures are usually a source of anxiety for children and are often painful. These procedures include routine immunization injections, venipuncture, and pelvic examinations. Reductions in anxiety and pain have been noted in children who were taught skills using hypnosis techniques. A randomized controlled study assessing the effects of hypnosis on distress of children undergoing a voiding cystourethrogram procedure found significant reductions in distress for the group of children who received hypnosis.

**BOX 56-7 Case Report—Migraine Headache**

Anne, an 11-year-old girl, had a history of migraine headaches for 3 years. Her mother also had migraines since childhood. Anne was evaluated by a child neurologist who, at various times, had prescribed propranolol, Periactin, and Elavil. He also suggested regular sleep and avoidance of certain foods.

Anne did well in school and had many friends. She enjoyed music and played the piano. She had two younger siblings, ages 8 and 6. She said that she was afraid of thunder.

At the initial visit, Anne was having a migraine episode at least once a week. Most episodes were preceded by a visual aura, and they lasted approximately 12 hours. They were accompanied by nausea and sometimes vomiting. Anne said that she would sleep as soon as possible after a migraine began and would usually awaken without the pain, but with a shaky feeling that lasted for several hours thereafter.

Anne was interested in learning self-hypnosis for control of her migraines. Anne chose to focus on music for her hypnotic induction. She imagined her favorite music as she gradually relaxed all of her muscles. She did well during the first practice.

At her second visit, Anne's finger temperature was monitored during her examination. Her peripheral temperature increased 4°F during this practice, proof that she was relaxing. She learned about pain signals and was offered options for turning the signals off if she should develop a migraine episode.

The third visit took place 3 weeks later. Anne had had 1 migraine during the period between visits, a significant decrease. Subsequently, she was followed up by telephone. In the 6-month follow-up period, she had 2 migraine episodes, both associated with sleep deprivation.

**BOX 56-8 Case Report—Warts**

David, age 7, had had warts on his hands and legs for 2 years. He had been treated by a dermatologist with topical treatments and freezing the warts. Each time, the warts recurred. David had 3 warts on his left leg, 3 on the right leg, 2 on the left hand, and 5 on the right hand.

David was in second grade. He enjoyed school and had friends in both school and the neighborhood. He liked bicycle riding, playing soccer, and ice skating. David had an older sister and a younger brother. He said he wanted to get rid of the warts because he did not like the way they looked and because the previous treatments hurt.

David was told that many children had eliminated warts by doing a relaxation exercise and giving a message to themselves to stop feeding the warts. He was told about practice at home and about the need for a good reminder system for the practice; his mother was told not to remind him to practice.

David imagined himself playing soccer as a hypnotic induction and was asked to imagine playing until the game was won, and then to tell himself to stop feeding each of the 13 warts.

David returned in 2 weeks. At this point, David had 7 warts and was very pleased. He continued practice for another month, and 12 of the warts were gone. No new warts appeared. After 3 months, all the warts were gone.

**HYPNOSIS IN THE ROUTINE PEDIATRIC OFFICE VISIT**

Integrating self-regulation techniques into primary care practice offers the opportunity for pediatricians and other child health professionals to facilitate a sense of mastery and competency in the children under their care. Although many physicians may not realize it, they have long been applying some of the hypnotic principles and using some of the sensitive language in their clinical work with children. In an introductory course on hypnosis, clinicians become aware of the importance of carefully selecting their language and monitoring the timing and pacing with which to introduce new words in their encounters with children. Clinicians often realize that integrating these techniques will be easier and faster than they may have originally believed.

Brief self-regulation interventions can be integrated into primary care practice. Following are some examples of simple techniques that can be used to

make a child more comfortable during routine office procedures such as receiving shots or throat cultures, or just being examined by a stranger.

- Having a child *blow away* pain by using a pinwheel, bubbles, or a pretend candle is an effective tool for decreasing a child's experience of pain during injections or venipuncture.
- Bubbles can also be used to get the attention of the young child who starts screaming as soon as the pediatrician walks into the room and to help the child to feel more comfortable.
- A stuffed animal or doll can be used as an example before examining a child. By pointing out how the doll or stuffed animal is comfortable being examined, the pediatrician can often help the child become more comfortable when being examined.
- A child who needs a throat culture may be able to use slow, deep breaths while focusing on a pleasant thought to keep still while keeping his or her mouth open.
- Favorite music can also be a good way to help the child focus and relax during procedures.

**BOX 56-9 Training Organizations**

- National Pediatric Hypnosis Training Institute ([www.nphti.org](http://www.nphti.org))
- Society for Clinical and Experimental Hypnosis ([www.sceh.us](http://www.sceh.us))
- American Society of Clinical Hypnosis (training workshops bimonthly) ([www.asch.net](http://www.asch.net))

How can the pediatrician or child health professional learn to use hypnosis in the practice?

1. *Take a basic 3-day hypnosis-training workshop.* See Box 56-9.
2. *Identify and stay in touch with a mentor after the first workshop.* Most of the workshops will offer mentoring assistance to encourage the new learner and provide advice regarding clinical situations. Workshops also have an active listserv resource for child health professionals who share knowledge about using hypnosis in a pediatric setting.
3. *Take follow-up workshops, read textbooks and hypnosis journals, and attend annual hypnosis scientific meetings.*
4. *Take board-certified examination in hypnosis.* Tests from the American Board of Medical Hypnosis, Hypnosis in Psychology, Hypnosis in Dentistry, and Hypnosis in Social Work are available. Information can be obtained from the American Society of Clinical Hypnosis or the Society for Clinical and Experimental Hypnosis.

**RESEARCH IN CHILD HYPNOSIS**

Active research in child hypnosis has taken place over the last 40 years. Initial research examined measures of child hypnotic susceptibility, such as the Stanford Children's Hypnotic Susceptibility Scale. Most subsequent research has been clinical research documenting the efficacy of hypnosis with children in areas such as pain management, habit problems, wart reduction, and performance anxiety. The variability in preferences, learning styles, and developmental stages complicates the design of research protocols for the study of hypnosis with children. These protocols are often written to describe identical hypnotic inductions, often recorded, to be used at prescribed times. Measured variables do not address whether a child likes the induction or listens to the tape, or whether the child focuses on entirely different mental imagery of the child's own choosing. Furthermore, learning disabilities are often subtle and may not be recognized without detailed testing that is not usually done before research studies involving child hypnosis. Learning disabilities, such as auditory processing disorder, may interfere with the ability of children to learn and remember self-hypnosis training. Each of these variables complicates efforts to perform meta-analyses on hypnosis and related interventions. Interventions called *relaxation imagery*, *imagery*, *visual imagery*, or *progressive relaxation* each lead to a hypnotic state. The proper analysis of studies on the efficacy of hypnosis in children should combine all

studies that describe strategies for inducing hypnosis in children.

Some research studies are defined as controlled but mix therapeutic interventions. For example, Scharff, Marcus, and Masek reported on "[a] controlled study of minimal-contact thermal biofeedback treatment in children with migraine." Children were randomly assigned to thermal biofeedback, attention, or wait-list control groups. The hand-warming biofeedback group received four sessions of cognitive behavioral stress management training, thermal biofeedback, progressive muscle relaxation, imagery training of warm places, and deep-breathing techniques. Thus, children were also being taught self-hypnosis.

Several controlled laboratory studies have demonstrated that an association exists between learning self-hypnosis and changes in humoral or cellular immunity (or both) in children. In one study, Karen Olness and colleagues examined the self-regulation of salivary immunoglobulin A by children, demonstrating that self-hypnosis can facilitate some immunomodulation in children. This work was the basis for a clinical trial by Hewson-Bower, who demonstrated that training in self-hypnosis for children with frequent upper respiratory tract infections resulted in a reduction of infectious episodes and fewer illness days when upper respiratory tract infections did occur.

An overview describing clinical and research evidence was recently published. The International Society of Hypnosis is currently sponsoring Cochrane reviews of hypnotherapeutic interventions, including those with children.

## Chapter 57

# COMPLEMENTARY AND INTEGRATIVE MEDICAL THERAPIES

Gregory A. Plotnikoff, MD, MTS; Kathi J. Kemper, MD, MPH;  
Timothy P. Culbert, MD

Interest in complementary and integrative medicine (CIM) has redefined modern Western medicine. Formerly unconventional therapies such as acupuncture, biofeedback, guided imagery, and hypnotherapy have been integrated into pediatric care in many clinics and hospitals (see Chapter 56, Self-Regulation Therapies: Hypnosis and Biofeedback). Other therapies such as herbs, dietary supplements, massage, and chiropractic care are widely used by the public and are increasingly available at conventional hospitals. Formal definitions of health care quality now acknowledge the importance of respecting spirituality and culturally based healing traditions in daily practice. The growing practice of providing care in a medical home emphasizes the importance of patient- and family-centered, relationship-based care that is at the heart of both pediatrics and integrative medicine. Pediatrics, more than most other specialties, embraces integrative medicine's emphasis on prevention and health promotion.

As found by Kemper and O'Connor, most pediatricians reported that they have limited knowledge of CIM and desired to know more; 70% of pediatricians reported having patients who use CIM therapies, 51% reported that they were concerned that CIM use by patients might delay standard medical care, and 36% were concerned that CIM use occasionally impairs physician-patient communication. However, fewer than 20% of pediatricians routinely ask about the use of CIM therapies. Most (83%) wanted to learn more about complementary and alternative therapies so that they might appropriately counsel families interested in them. Specialists as well as generalist pediatricians need to know about integrative care because the use of CIM therapies is particularly high among children with multiple chronic conditions who seek specialist care.

Similarly, most parents report the desire to discuss CIM with their pediatrician. This group includes more than 80% of those who use CIM for their children. However, fewer than one-half of these parents report having done so. Lack of communication may compromise the quality of care.

Pediatric integrative medicine (PIM) represents one of the newest subspecialties in the care of children. In North America alone, there are more than 15 academic

pediatric programs where clinical care, resident teaching, and research are conducted. However, pediatricians do not need to be content experts on every CIM therapy and product or seek specialized training. Nor do they need to reject their training in biopsychosocial medicine or critical thinking. However, the tremendous growth in demand for CIM plus use of the Internet and mass media for health information suggests the necessity for new competencies in pediatric care. The 21st century pediatrician should have the capacity to do the following:

- Focus on patient and family health goals in addition to diagnostic labels
- Inquire regarding CIM use
- Counsel on CIM from an evidence-based perspective using proven behavioral techniques to foster healthy lifestyles
- Partner with and refer appropriately to CIM practitioners
- Monitor for potential adverse side effects

This chapter defines CIM and describes how to inquire, counsel, partner, and refer. For physicians who seek further skills development, Box 57-1 also cites additional physician training opportunities.

## WHAT IS COMPLEMENTARY AND INTEGRATIVE MEDICINE?

Complementary and integrative medicine includes all health care systems, therapies, and products that are not considered part of conventional medicine as

practiced in the United States. These therapies can be used to supplement conventional care, thus the term *complementary*. When prescribed by physicians as part of a comprehensive treatment plan, they are considered integrative. Because the term *alternative* meant in place of conventional medical care, the term has been dropped by both physicians and the National Institutes of Health. The term *integrative medicine* has been adopted by the American Academy of Pediatrics and is represented by the Section on Integrative Medicine.

Integrative medicine represents the ideal of a higher-order system of care rather than simply the addition of complementary therapies to conventional care. The Consortium of Academic Health Centers for Integrative Medicine, which consists of 56 academic medical centers, defines integrative medicine as follows:

[T]he practice of medicine that reaffirms the importance of the relationship between physician and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, health care professionals and disciplines to achieve optimal health and healing.

Integrative medicine emphasizes the centrality of the therapeutic relationship, the importance of prevention, and the healing power of nature. Integrative medicine seeks to use the best of scientifically based medical therapies along with compassion and attention to the patient's spiritual and emotional needs, as well as appropriate complementary and alternative approaches when they enhance conventional medicine. Some argue that integrative medicine is simply good pediatric care.

The National Institutes of Health 2001 survey of 31,044 adults assessed and ranked the use of 5 categories of CIM: mind-body medicine, biologically based therapies, manipulative and body-based methods, alternative medical systems, and energy therapies. However, since 1996, pediatricians have embraced a more synergistic model of 4 categories of integrative complementary and alternative medicine and conventional therapies: lifestyle (healthy habits in a healthy habitat); biochemical (medications and supplements); biomechanical (surgery, massage, manipulative therapies); and biofield (acupuncture, prayer, and homeopathy).

### Lifestyle Strategies

Healthy lifestyle habits are the keys to good health throughout the life span. Healthy habits include the following:

- Healthy nutrition (and avoiding toxins like tobacco)
- Healthy physical activity
- Healthy sleep
- Healthy emotional and mental self-regulation
- Healthy social relationships

A healthy habitat refers to the physical, psychological, social, educational, and political environment. For example, music and spending time in nature offer therapeutic benefits to children of all ages.

Because pediatricians are familiar with most of these habits, this chapter will focus on healthy emotional and mental self-regulation. Although conventional care typically refers to mental and behavioral

health, psychotherapy, and support groups, integrative care also includes mind-body strategies such as biofeedback, meditation, hypnosis, guided imagery, and yoga. The purpose of using these strategies is to achieve optimal mental and emotional health and enhance resilience.

Mind-body medicine includes all therapies that activate emotional, mental, spiritual, and behavioral factors to modulate positively physiologic mechanisms, including immune and endocrine function. Over 35 years ago, Green, Green, and Walters stated that

... every change in the physiologic state is accompanied by an appropriate change in the mental-emotional state, conscious or unconscious, and every change in the mental-emotional state is accompanied by an appropriate change in the physiologic state.

The bidirectional influences of mind on body and body on mind can have significant mediating effects, both positive and negative, on health outcomes for children. In the past 20 years, mind-body therapies have become recognized as safe and effective for many pediatric conditions, including headaches, asthma, enuresis, sleep problems, pain, and stress-related symptoms.

According to the National Institutes of Health, spiritual and religious practices such as prayer represent the most prevalent complementary therapies in the United States. Nearly 80% of US adults think that religion, to a large extent, helps patients and families cope with illness. Nearly 75% of the public think that praying for someone else can help cure that person's illness, and 56% of adults state that faith has helped them recover from illness, injury, or disease. Spirituality may or may not involve formal religion. Spiritual concerns arise in clinical settings when important connections with self, with others, with nature, and with a higher power are threatened or disrupted. Spiritual beliefs are frequently important in medical decisions. Spiritual well-being is closely linked to successful coping, faster recovery, and higher quality of life. Many patients may want help with meaning, hope, or overcoming fears, and unmet spiritual needs are associated with despair and increased mortality. Parents often have significant spiritual needs around the life-threatening illness or death of a child.

A growing body of research has demonstrated the benefits of various kinds of meditative practices to train the mind and regulate the emotions, resulting in less pain and fewer symptoms in children and adults. For example, training in mindfulness-based stress reduction and mindfulness-based cognitive behavioral therapy decreased psychological distress among adolescents with psychiatric disorders and decreased hostility and stress among urban youth. Moving meditation practices such as tai chi and yoga can also improve behavior, mental health, physical symptoms, and physical fitness.

Music and music therapy—the intentional use of melody, rhythm, harmony, timbre, form, and style for healing—are important contributors to well-being. In premature infants, music therapy can lower heart and respiratory rates, increase oxygen saturation, improve sleep patterns, improve sucking behaviors, improve caloric intake and weight gain, and decrease

salivary cortisol and distress behaviors. Music also can significantly reduce the stress parents associate with premature infant care. In postsurgical patients, intraoperative and postoperative music reduces both pain and pharmaceutical requirements, including use of both sedatives and analgesics. This seems to be true for procedures as well. In pediatric oncology patients, music therapy can reduce pain and suffering and improve both mood and attitude. In intensive care units, music reduces patient anxiety and depression; and for dying patients, music therapy has been shown to improve the quality of life.

Mind-body therapists may include physicians, psychologists, meditation instructors, nurses, social workers, chaplains, music therapists, and registered yoga teachers. Frequently, master's level and higher levels of education in these fields include training in 1 or more mind-body therapies. Formal graduate-level training is required for both chaplaincy and music therapy certification.

### Biochemical Therapies

Biochemical therapies include both medications and natural products such as herbs, vitamins, and other supplements. Vitamin K is recommended for all children to prevent hemorrhagic disease of the newborn, and supplemental vitamin D is recommended for breastfed infants. The most recent data show that 46.2% of 1,280 interviewed adolescents had used dietary supplements in their life, with 29.1% having used a supplement in the previous month. Nearly 10% of adolescents report using supplements with prescription medications in the previous month. Children with chronic or recurrent illnesses often turn to herbs and other dietary supplements.

The most frequently used supplements in children (aside from vitamins D and K) are multivitamins, single vitamins, and minerals (eg, vitamin C, iron, and calcium). The most frequently used herbal products in children include chamomile, peppermint, echinacea, and aromatherapies such as lavender. In adolescents, the use of weight-loss supplements and creatine are closely linked to attempts to change body shape.

Since the passage of the Dietary Supplement Health and Education Act of 1994 (DSHEA), supplements have been regulated by the US Food and Drug Administration (FDA) with requirements more akin to foods than drugs. Good Manufacturing Practice (GMP) regulations are identical to those for food. Unlike food and drugs, dietary supplements can be sold without premarket approval and do not require a specific post-marketing study. Supplements can be sold based on evidence of safety in the possession of the manufacturer. Supplements can only be removed from the market if the FDA can prove them to be unsafe under ordinary conditions of use. This ban recently occurred with the sympathomimetic herb ephedra (*Ephedra sinica* and related plants), which had been widely marketed for weight reduction. The FDA ruling was later overturned in a court ruling.

Under DSHEA, herbal medicines can be sold for *stimulating, maintaining, supporting, regulating, and promoting health* rather than for treating disease. As

dietary supplements rather than drugs, herbal medicines may not claim to restore normal or to correct abnormal function. Additionally, herbs may not claim to *diagnose, treat, prevent, cure, or mitigate*. For example, herbal medicine companies can assert that their product supports cardiovascular health but not that it lowers cholesterol. To do so would suggest that the product is for treating a disease (hypercholesterolemia) and is therefore subject to FDA pharmaceutical regulations. However, most herbs are used by the public for the treatment of a disease or symptoms of a disease (Table 57-1). Only functional foods (eg, oat bran, soy, cranberries, certain processed butter-like spreads) can claim specific health benefits. Such approvals require significant supporting clinical data and FDA approval.

Licensed practitioners who promote herbal medicine use include naturopaths and chiropractors for whom advanced training often exists as part of their degree programs or continuing education programs. Not all naturopaths, however, are graduates of accredited naturopathic medical schools. International Board Certified Lactation Consultants frequently prescribe herbs such as fenugreek to nursing mothers to stimulate milk production. Reliable resources (Box 57-2) describing herbal medicine and supplements are useful.

### Biomechanical Therapies

Manipulative and body-based methods include all therapies that focus on manipulation and movement of one or more parts of the body. The best-known examples are chiropractic, osteopathy, and massage. All examples incorporate touch, an essential human need with therapeutic, interpersonal, and cultural dimensions. Massage is one of the oldest health care practices and was used in ancient times in India, China, Arabia, Egypt, and Greece. Experience at one of the largest pediatric CIM programs at a children's hospital in the Midwest suggests that massage and other forms of bodywork are among the most popular options—inpatient or outpatient—selected by children and teens. Similar observations have been documented in pediatric oncology patients and adolescents. Massage may be provided most often by parents or other family members. The appropriate amount of massage has not yet been measured, but family members frequently appreciate the chance to learn a skill that can contribute to the comfort and well-being of the patient. Massage can also include many different techniques and forms that require more significant training, including structural integration (Rolfing), movement integration (Feldenkrais technique, Alexander technique), pressure point techniques (shiatsu, acupressure), cranial sacral therapy, reflexology, and many others.

The manipulation, compression, and stretching of the skin, muscles, and joints activates a variety of mechanisms that support and promote health, including the following:

- Mechanical—enhances blood flow to the muscles and soft tissues and enhances lymphatic flow
- Immunologic—enhances specific immune cell functions such as natural killer cell activity

**Table 57-1** Commonly Used Herbal Therapies

COMMON NAME (LATIN NAME)	COMMON USES
Aloe ( <i>Aloe vera</i> )	Burns, minor wounds, skin irritations, aphthous stomatitis, constipation, gastric and duodenal ulcers
Astragalus ( <i>Astragalus</i> species)	Immune booster
Calendula ( <i>Calendula officinalis</i> )	Skin soother
Cascara ( <i>Rhamnus purshiana</i> )	Constipation
Cayenne ( <i>Capsicum frutescens</i> )	Topical treatment for pain, postherpetic neuralgia, nasal spray for migraines and cluster headaches
Chamomile ( <i>Matricaria recutita</i> )	Sedative, colic, anti-inflammatory, antispasmodic
Clove oil ( <i>Syzygium aromaticum</i> )	Teething pain
Coffee ( <i>Coffea</i> species)	Stimulant, attention-deficit/hyperactivity disorder, bronchodilator
Curcumin ( <i>Zingiberaceae</i> )	Anti-inflammatory, antioxidant
Dandelion ( <i>Taraxacum officinale</i> )	Mild diuretic, liver tonic
Dill ( <i>Anethum graveolens</i> )	Antispasmodic, provides colic relief, decreases flatulence
Echinacea ( <i>Echinacea</i> species)	Immune stimulation, anti-inflammatory
Ephedra (ma huang) ( <i>Ephedra</i> species)	Vasoconstriction; allergy, upper respiratory infection; asthma; appetite suppressant
Evening primrose oil ( <i>Oenothera biennis</i> )	Eczema, premenstrual syndrome
Fennel ( <i>Foeniculum vulgare</i> )	Colic
Feverfew ( <i>Tanacetum parthenium</i> )	Migraine headaches, rheumatoid arthritis
Garlic ( <i>Allium sativum</i> )	Antimicrobial, cholesterol lowering
Ginger ( <i>Zingiber officinale</i> )	Antiemetic, antinausea
Ginkgo ( <i>Ginkgo biloba</i> )	Enhances blood flow past clogged arteries; prevents memory loss; marketed to treat attention-deficit/hyperactivity disorder
Ginseng ( <i>Panax</i> species)	Stimulant, adaptogen; enhances endurance and performance
Hawthorn ( <i>Crataegus oxyacantha</i> )	Cardiac stimulant; enhances cardiac contractility
Hops ( <i>Humulus lupulus</i> )	Sedative
Kava kava ( <i>Piper methysticum</i> )	Anxiolytic
Lavender ( <i>Lavendula</i> species)	Sedative
Licorice ( <i>Glycyrrhiza</i> species)	Anti-inflammatory, antiviral, demulcent
Milk thistle ( <i>Silybum marianum</i> )	Hepatoprotection against cirrhosis, hepatitis
Oats ( <i>Avena sativa</i> )	Antipruritic; eczema, varicella
Pine bark extract ( <i>Pinus</i> species)	Antioxidant promoted to treat attention-deficit/hyperactivity disorder
Rhubarb root ( <i>Rheum officinale</i> )	Constipation, chronic renal failure
Saint John's wort ( <i>Hypericum perforatum</i> )	Depression, antiviral
Skullcap ( <i>Scutellaria</i> species)	Sedative
Slippery elm bark ( <i>Ulmus fulva</i> )	Demulcent; pharyngitis
Stinging nettle ( <i>Urtica dioica</i> , <i>Urtica urens</i> )	Hay fever
Tea tree oil ( <i>Melaleuca alternifolia</i> )	Topical antimicrobial; treats acne, minor skin infections, including fungal and yeast infections
Thyme ( <i>Thymus vulgaris</i> )	Antimicrobial, expectorant; treats colds, sore throats, cough
Valerian ( <i>Valeriana officinalis</i> )	Sedative
Witch hazel ( <i>Hamamelis virginiana</i> )	Topical antiseptic, anti-inflammatory

- Neurologic—triggers relaxation response and lowers sympathetic nervous system arousal, reduces serum cortisol, enhances endogenous serotonin and dopamine levels, and modulates pain perception
  - Energetic—according to traditional thought, certain massage practices can provide balance and improve the flow of life force energy or *chi*
- Massage can be enhanced with a biochemical therapy—aromatherapy—the therapeutic application of essential oils distilled from plants. Specific scents are targeted to specific symptoms, such as lavender or chamomile for relaxation, ginger or spearmint for nausea, and peppermint or lemon for fatigue.

Chiropractors are licensed in all 50 states, and their services are widely covered by insurance, including

Medicaid. Most chiropractic schools offer courses in pediatric care. Chiropractors can use special pediatric tables and gentle techniques, or treat the children in their parents' laps. Massage therapists are also licensed in all 50 states, but training and licensure requirements are quite variable. The largest professional national organization of bodyworkers is the American Massage Therapy Association. Membership requires training in an accredited school and completion of 500 hours of training.

### Biofield Therapies

Biofield therapies include practices that invoke, stimulate, or alter an invisible energy, spirit, or information to achieve a health goal. In conventional medicine,

radiation therapy is used to treat cancer and invisible rays are used to diagnose illnesses with x-rays and ultrasound. In Asian cultures, an invisible energy or life force is known as chi, which can be affected by acupuncture and related practices. In some religious and secular traditions, healing energy can be sent by prayer, good wishes, laying on of hands, Therapeutic Touch, Healing Touch, or Reiki. In homeopathy, an original compound that causes a symptom is diluted so much that what remains has energy or information to combat that symptom.

Among major teaching hospitals that have a pediatric pain service, 33% offer acupuncture therapy to treat pain. Additional indications may include constipation and traumatic brain injury. Acupuncture is quite safe, even with cancer-associated thrombocytopenia, and can be an effective and well-accepted intervention with children and teens. Use of the term *acupoint stimulation* avoids eliciting fear of needles. Acupoint stimulation can be achieved by massage, comfortable electrical stimulation, stickers with beads, or very thin (>30 gauge) nonhollow acupuncture needles. In many instances, after gradually establishing comfort and trust with a noninvasive approach, children and teens will agree to needle insertion. Acupuncture, when done correctly, is virtually painless and well tolerated for older children.

Acupuncturists are licensed in more than 40 states. In most states, licensed health professionals such as physicians can practice acupuncture. Insurance plans increasingly offer acupuncture for chronic pain and chemotherapy-induced nausea and vomiting.

### Therapeutic Touch

Therapeutic Touch, Healing Touch, and Reiki are all secular forms of laying-on-of-hands healing. Actual touching the patient does not always take place because the human energy field, like the electromagnetic field, extends beyond the skin into the space surrounding the body. Therapeutic Touch was invented in the 1970s by a New York University nursing

professor, Dolores Krieger, and a lay healer, Dora Kunz. Based on their observations of numerous religious healers, they distilled the process into 5 steps that practitioners might bring to healing outside of a specific religious faith or belief. These steps are:

1. Having a clear and conscious intent to be helpful and heal
2. Being centered in a peaceful state of mind
3. Using hands to assess the patient's energy (typically moving the hands 1 to 3 inches away from the body in a slow downward sweep from the head to the toes)
4. Using hands to help restore the patient's energy to a balanced, harmonious, peaceful state
5. Releasing the patient to complete the healing process while the healer returns to the healer's own centered, peaceful state of mind

Nurses and other health professionals in more than 80 countries have received training in Therapeutic Touch from its founders. It is currently taught in nursing schools across the United States. Nursing practice in many hospitals, including children's hospitals, includes policies and procedures for performing Therapeutic Touch.

Additional techniques have been added to Therapeutic Touch in a group of treatments called Healing Touch, which is largely practiced by holistic nurses. Small studies have suggested that Healing Touch can help decrease stress and improve autonomic balance in pediatric oncology patients.

Reiki is a similar practice that comes from a Japanese tradition. Practitioners are trained by a Reiki master through apprenticeship and spiritual and energetic initiation. Neither Therapeutic Touch nor Reiki has national certifying examinations or state licensure. Therapeutic Touch and Healing Touch are typically provided by nurses in both inpatient and outpatient settings. Reiki is typically provided by lay practitioners outside of medical settings. No reports of side effects have been documented from such treatments. The primary clinical benefits of Therapeutic Touch are increased relaxation, diminished anxiety, diminished pain, and enhanced sense of well-being.

In addition to Therapeutic Touch and Reiki, some practitioners use electromagnetic or static magnetic fields to reduce pain or speed healing. For example, pulsed electromagnetic fields are used to promote union of long-bone fractures. There is growing research on the use of pulsed electromagnetic fields for fracture and wound healing in pediatrics. Growing research also supports the use of static magnetic fields to reduce pain and inflammation.

### Homeopathy

Homeopathy is a system of medical treatment invented in the early 1800s by the German physician Samuel Hahnemann. Homeopathy was frequently taught and practiced in US medical schools until criticized in the 1910 Flexner Report. Currently, homeopathy is popular in Europe, Russia, India, and South America.

Homeopathy is based on 2 principles: the *Law of Similars* or *like cures like* and the *Law of Dilutions*. The Law of Similars means that a remedy that would cause

a symptom in a healthy person is used to treat the same symptom in a sick person. For example, a treatment, termed remedy, made from the poison ivy plant (*Rhus toxicum*) might be used to treat a child suffering from eczema. Although pediatricians might be concerned about dangerous-sounding homeopathic medications such as *belladonna*, serious side effects from homeopathic treatment are exceedingly rare, far less common than side effects from standard over-the-counter and prescription medications.

Homeopathy's safety is attributable to homeopathy's second principle, the Law of Dilutions, which states that the more a remedy is diluted, the more powerful it becomes. Dilutions of 1 to 10 are designated by the Roman numeral X (1X = 1/10, 3X = 1/1,000, 6X = 1/1,000,000). Similarly, dilutions of 1 to 100 are designated by the Roman numeral C (1C = 1/100, 3C = 1/1,000,000, and so on). Most remedies today range from 6X to 30X, but some products are as dilute as 200C. Dilutions beyond 12X or 24C contain none of the original molecules. Common over-the-counter remedies include combination products for teething, colic, allergies, and bedwetting.

Homeopaths think that these highly dilute solutions contain an energy, or information, that the patient uses to heal symptoms. Many physicians think that the remedies are placebos that trigger the patient's psychoneuroimmunologic healing systems. Randomized controlled trials suggest some support for homeopathic remedies for diarrhea and otitis media but not for attention-deficit disorder.

The private, nonprofit Council for Homeopathy Education reviews homeopathic programs. Certification in homeopathy is given after testing by the Council. Certification boards exist for health care professionals, including physicians (American Institute of Homeopathy), chiropractors (National Board of Homeopathic Education), and naturopaths (Naturopathic Academy of Homeopathic Physicians). Persons who are not health care professionals are registered with the North American Society of Homeopaths.

## TALKING WITH PATIENTS ABOUT COMPLEMENTARY AND INTEGRATIVE MEDICINE

Although many physicians are concerned that families who use CIM may be dissatisfied with mainstream medical care and fear they may abandon effective therapies in favor of unproved alternatives, data do not support these concerns. Fifty-five percent of all surveyed adults think that CIM therapies would support health when used with conventional medical treatments. For the most part, families seek therapies that are consistent with their values, worldview, and culture, and they seek care from therapists who respect them as individuals and who offer them time and attention. Families continue to value highly the care they receive from compassionate, comprehensive primary care pediatricians, and they seek additional information on healthy lifestyles, dietary supplements, and environmental therapies over which they may exert some control. They also seek care from therapists who offer personal attention, hope,

time, and therapies that are consistent with their culture and values. Families who seek out CIM therapies rarely abandon their pediatrician, but they may not feel comfortable discussing these therapies if they perceive the pediatrician to be antagonistic or judgmental toward them.

To provide the best care, pediatricians should ask all patients about all the therapies they use to promote health. This task is best accomplished in a seamless, structured, and nonjudgmental manner during the medical interview. To set a positive tone, the physician can begin new patient interviews with questions about the number of meals eaten together as a family, fun things the family does together, hopes and dreams for the child, and aspects of the child of which they are most proud. At each return visit, a helpful question would be, "Since the last visit, which other health professionals has your child visited?" As with all good interviewing, listening for understanding rather than agreement or disagreement enhances the therapeutic alliance.

### Social History

During the social history, the physician should inquire about the following:

- Diet, exercise, and environment (including use of music to manage stress) to provide insight about risks and actions taken to promote health
- Illness care at home
- Any special foods, teas, rubs, prayers, or rituals that are helpful for the patient's family
- Any mind-body therapies to manage stress, reduce chronic symptoms, or promote well-being such as deep breathing, yoga, meditation, or prayer

One such question might be, "When you are stressed, what is most helpful for you? Which of your activities do you find is best for your health?" To assess psychological wellness, stress and time management, self-esteem, and self-concept, a thorough academic history and questions about learning style, friends, hobbies, and extracurricular activities should be included.

Questions regarding spirituality can be inserted at this point in the inquiry, as appropriate. Multiple mnemonics exist to guide physicians in their interviews to understand the patient's and family's source of meaning, purpose, richness, and direction (Box 57-3). Conscious choices expressed in the social history represent strengths that can be used for achieving health goals. Clearly, ethical boundaries exist around faith and spirituality. The physician's role is not to provide answers but to support the search for answers.

This point of the inquiry is also the time for assessing all potential environmental factors contributing to health and illness in children. A useful mnemonic for an environmental history is ACHHOO, with each letter representing a potential exposure site to known toxins such as lead, mercury, secondhand tobacco smoke, pesticides, and other contaminants:

- Activities
- Community
- Household
- Hobbies
- Occupation
- Oral behaviors

**BOX 57-3 Spiritual Assessment Tools****FICA****F: Faith or belief**—What is your faith or belief?**I: Importance and influence**—Is faith important in your life? How?**C: Community**—Are you part of a religious community?**A: Awareness and addressing**—What would you want me as your physician to be aware of? How would you like me to address these issues in your care?**HOPE****H: Hope**—What are your sources of hope, meaning, strength, peace, love, and connectedness?**O: Organization**—Do you consider yourself part of an organized religion?**P: Personal spirituality and practices**—What aspects of your spirituality or spiritual practices do you find most helpful?**E: Effects**—How do your beliefs affect the kind of medical care you would like me to provide?**SPIRIT****S: Spiritual belief system**—What is your formal religious affiliation?**P: Personal spirituality**—Describe the beliefs and practices of your religion or spiritual system that you personally accept or do not accept.**I: Integration within a spiritual community**—Do you belong to a spiritual or religious group or community? What importance does this group have for you?**R: Ritualized practices and restrictions**—Are there specific practices that you carry out as part of your religion/spirituality (eg, prayer or meditation)?**I: Implications for medical care**—Would you like to discuss religious or spiritual implications of health care?**T: Terminal events planning**—As we plan for your care near the end of life, how does your faith affect your decisions? Are there particular aspects of care that you wish to forgo or have withheld because of your faith?

Adapted from Puchalski CM, Romer AL. Taking a spiritual history allows physicians to understand patients more fully. *J Pall Med.* 2000;3:129–137; Anandarajah G, Hight E. Spirituality and medical practice: using the HOPE questions as a practical tool for spiritual assessment. *Am Fam Physician.* 2001;63:81–88; and Mougans TA. The SPIRITual history. *Arch Fam Med.* 1996;5:11–16.

**Allergies and Current and Past Medications**

When documenting current and past medication use, additional questions to ask in routine practice include the following:

1. Do you use multivitamins, for example, Poly-Vi-Sol or Flintstones chewable vitamins?
2. Do you use over-the-counter medications, for example, any medications for colds, pain, or constipation?
3. Do you use herbal medicines, for example, any herbs such as echinacea or chamomile?
4. Do you take specific vitamins and minerals, for example, vitamin C, D, or E? Do you take any mineral supplements such as calcium, iron, magnesium, or selenium?
5. Do you take dietary supplements, for example, any supplements such as fish oils, melatonin, or probiotics?

Follow-up questions include the following:

- What brand?
- What dose?
- How often?
- What directions are you following?
- What goals are you hoping to achieve by taking it?
- Are you using any other remedies now?

Understanding the supplements used and the patient's and family's source of information for making treatment decisions can be quite helpful for comprehending what is important to the family.

Interviewing for supplement use is crucial for identifying patients who are at risk for interactions with prescription medications or for excessive bleeding in surgery. Too frequently, professionals and patients follow a *don't ask, don't tell* policy. *Ask, provide an example, then ask again* is a practice policy that is foundational to safe and effective patient care.

Patients should be asked to bring all remedies with them to every visit so that the chart can be updated and usage monitored. Patients with special risks of drug interactions include those who take anticoagulants, hypoglycemics, antidepressants, sedative-hypnotics, antihypertensives, and medications with narrow therapeutic windows such as digoxin and theophylline.

**Medical History**

In addition to immunizations, surgeries, and hospitalizations, the interview for the medical history is a good time to ask about other therapies that often require multiple visits, such as chiropractic, massage, and acupuncture. Understanding what worked or did not work for the patient provides further insights into what is important for the patient and family. Additionally, questioning during this portion of the inquiry can help identify health issues that may be important to address in the context of a holistic approach to health.

**COUNSELING FAMILIES ABOUT COMPLEMENTARY AND INTEGRATIVE MEDICINE**

The goal of counseling is to strengthen the physician–patient relationship through honest dialogue that is clinically responsible, ethically appropriate, and legally defensible. Parental inclusion of CIM therapies for their children, in itself, does not constitute child neglect. Similarly, physician provision of complementary and alternative therapies does not, in itself, represent professional misconduct.

Increasingly, pediatricians will find themselves sharing patients with massage therapists, chiropractors, acupuncturists, and others. Pediatric patient advocacy requires assessing for safety and efficacy and respecting the autonomy of the parent–child relationship. When patients or families report seeing other health professionals and describe current CIM use, physicians should follow 3 steps in response to the answers provided:

Step 1. Determine whether the therapy represents a rejection of standard care for a serious or life-threatening disease for which a reasonable chance exists of cure or if use of the therapy will delay proven treatment. In such cases, the first step is to protect the child while understanding the parents' goals. Reporting requirements for abuse and neglect may apply. (See Chapter 367, Physical Abuse and Neglect.)

Step 2. Determine whether the therapies used are known to be unsafe, ineffective, or both. Excellent Web-based and other resources are noted at the end of this chapter to guide this assessment.

In the event of use of a known toxic agent or an ineffective agent with possible harm, the physician's responsibility is to counsel from the documented evidence that the therapy should be stopped. Resistance to such advice may place the parents at risk for charges of negligence or abuse.

In the absence of data on toxicity or efficacy, the pediatrician's role is to monitor as clinically appropriate. This role can include scheduling telephone follow-up or office visits. In both cases, document the following in the medical record:

- Therapy used and the goal of the therapy
- Patient or family preferences and expectations regarding the therapy
- Physician of the therapy, location, and treatment plan (as known by the family). This information should include names, telephone numbers, any other contact information, and specialties.
- Review of the safety and efficacy issues of the therapy from the medical literature

- Results of counseling including the pediatrician's treatment plan for monitoring the treatment and its results
- Advice provided or resources recommended for further information

Step 3. Ensure that the patient's and family's decision to use a therapy is based on a fully informed judgment and that their verbal consent was obtained and documented. This documentation includes what options have been discussed, offered, tried, or refused. (General guidelines for counseling are found in Box 57-4.) Counseling on spiritual concerns requires special consideration for clinical and ethical reasons. Although not classically part of medical training, adults in the United States consistently report that physicians talking with patients about spirituality is appropriate. When surveyed, 83% of 921 primary care patients surveyed in Ohio reported that they wanted physicians to ask about spiritual beliefs in certain circumstances, such as with serious illness or the loss of loved ones.

Spirituality may be understood as connection with the sources of ultimate meaning. Spirituality may or may not include formal religion. Spiritual concerns arise with threatened losses or disruptions of such connections. These issues can include key relationships with parents, other family members, and friends or what the child thinks God to be. For efficient and effective clinical care when spiritual issues are present, the following guidelines should be kept in mind:

1. Anticipate the presence of spiritual concerns with every illness. These concerns can include those of the patient, the family, and care team members, as well as one's own.
2. Comprehend how the patient's and the family's faith or spirituality can be a resource during illness.
3. Seek to understand how the patient's or the family's cultural and spiritual worldview influence understanding of the disease, the appropriate treatment, and the recovery process.

#### BOX 57-4 How to Talk With Patients About Complementary and Integrative Therapies

1. Do talk about the different kinds of therapies families may have tried to help their child.
2. Do not wait for families to bring it up.
3. Ask in an open-minded, nonjudgmental fashion. Avoid using potentially pejorative terms such as *unproved*, *unconventional*, or *alternative*.
4. Elicit further information with questions about specific therapies. For example, have you tried any *herbal* therapies, such as echinacea or ginkgo? Have you tried any *dietary* therapies, such as avoiding wheat or milk? Have you sought care from any *other health professionals*, such as acupuncturists or chiropractors?
5. Elicit the values, beliefs, and influences that led parents to these therapies. For example, were these suggested by family members? Were they consistent with their religious, spiritual, or cultural beliefs? What is the value of natural or organic approaches? Do they have a fear of side effects of mainstream treatments?
6. Whenever possible, join with the parents and support their decision to pursue avenues that may help their child. Be an ally rather than a tyrant.
7. Ask how well the family thinks the therapies worked or did not work *before* offering your opinion.
8. Offer to talk with other therapists involved in the child's care to maintain coordinated, comprehensive care.
9. Offer to learn more to help answer the family's questions.
10. Offer families additional information and resources to address their questions about alternative and complementary therapies.

4. Determine what effect, positive or negative, the patient's or the family's spiritual orientation or interpretation has on perceived needs.
5. Partner with, and refer to, chaplains or the patient's or the family's preferred spiritual care provider for assistance with significant spiritual concerns.

To achieve these goals, open-ended questions are always helpful. The physician should create a safe environment in which patients and families can articulate their questions. In contrast to the role of physicians in routine medical care, for spiritual concerns, solving problems and providing answers are rarely helpful. For spiritual concerns, the best answers are found rather than given. The physician's role is to support the search for answers.

## HOW TO PARTNER WITH OTHER PRACTITIONERS

Because of increasing interest and evidence of safety and efficacy, pediatricians increasingly want to partner with and refer to a growing number of diverse practitioners. This task is quite easy when credentialed practitioners exist in conventional settings such as hospital-based integrative pediatric clinics or consultation services. However, when a pediatrician provides the therapy or refers to practitioners in the community, the State Medical Board Guidelines apply. Key points include documenting the following in the medical record:

1. Parity of evaluation (medical history and physical examination as thorough as for conventional care)
2. Informed consent (review of diagnosis, all medical options for that diagnosis, discussion of risks and benefits of the recommended treatment, including potential interference with ongoing conventional care, and any applicable financial interests)
3. Treatment plan objectives and goals (expected favorable outcomes and monitoring plan for duration of treatment). Physicians should only refer to licensed or otherwise state-regulated health care practitioners with the requisite training and skills to use the therapy being recommended. Physicians are expected to not sell, rent, or lease health-related products or engage in personal branding. Physicians must also be able to demonstrate a basic understanding of the medical scientific knowledge connected with any recommended therapy.

Physicians are not liable for any negligence on the part of another physician unless the referral delayed necessary conventional treatment, the physician knew the provider was not competent to provide the therapy, or the physician hired the provider or provided joint treatment with the provider.

When making referrals for children with complex chronic illness or chronic pain, pediatricians must carefully prioritize and schedule necessary conventional therapies. They must also coordinate care with all subspecialists. Equally important, however, pediatricians must consider the effect on time and expenses of families who are vulnerable as they seek any available therapies for children. The pediatrician should set appropriate expectations, support appropriate hope, and avoid overscheduling and overtreating children.

## CONCLUSION

Increasingly, the public expects pediatricians to provide wise counsel on all reasonable available therapies and to make appropriate referrals based on scientific evidence and families' values and goals. There are many opportunities for pediatricians to seek additional training to enhance their clinical practice. Additionally, the American Academy of Pediatrics, the National Institutes of Health, and many other organizations provide additional resources to support pediatric service excellence.

## Chapter 58

# FLUIDS, ELECTROLYTES, AND ACID-BASE COMPOSITION

Prashant Mahajan, MD, MPH, MBA; Jon R. Felt, MD

Evaluating and managing fluid and electrolyte disorders in children requires an understanding of the composition of the human body and the regulatory mechanisms that maintain homeostasis. The primary care physician will encounter the issue of managing fluids and electrolytes in a large number of patients.

The optimal fluid and electrolyte solution varies depending on the age of the patient, cause of the disease, severity of the condition, and presence of a coexisting morbidity in the patient. Normal homeostasis is maintained by a complex interaction among the solutes, body water, hormonal influence, and the hypothalamic-pituitary-renal axis. Guiding the approach to fluid therapy in any child are a few basic principles of human physiology, including the regulation of body water, electrolytes, and acid-base equilibrium.

### BODY FLUID COMPARTMENTS

The entire body mass is composed of total body water (TBW) and body solids (fat, skeletal muscle, and cellular components). Traditionally, TBW has been viewed as a composite of intracellular fluid (ICF) and extracellular fluid (ECF), and it varies with sex, age, and fat content.

The size of the body's fluid compartments changes significantly in the first year of life. TBW comprises approximately 75% of an infant's mass and approximates the adult figure of 60% by 1 year of age. TBW varies inversely with the fat content of the body. TBW decreases in dehydration, becoming a smaller percentage of body weight.

The ECF is divided into intravascular fluid or plasma (5% of body weight) and interstitial fluid (15% of body weight) (Figure 58-1). The term *effective circulating volume* refers to the blood volume that is perfusing the tissues of the body and is in contact with and stimulating the volume and pressor receptors. The delicate balance between intravascular fluid and interstitial fluid is maintained by hydrostatic pressures (the result of the pumping action of the heart), as well as osmotic pressures and oncotic pressures (the result of the

presence of proteins, mainly albumin, in circulation). Pathologic conditions such as nephrotic syndrome reduce the plasma oncotic pressure and tend to increase the interstitial fluid volume at the expense of intravascular fluid volume, whereas states of dehydration cause a decrease in both interstitial and intravascular volume. ICF constitutes 40% of TBW and is separated from the ECF by cell membranes that are highly water permeable but selectively impermeable to solutes.

### ELECTROLYTE COMPOSITION

In plasma, sodium is the major cationic particle, with smaller concentrations of calcium, magnesium, and potassium present. Electroneutrality is maintained by an equal number of anionic particles, primarily chloride, bicarbonate, and protein. In addition to these particles are the unmeasured anions that are not part of the laboratory profile (the anion gap), namely phosphate, sulfate, and various organic acids.

The composition of ICF is different from that of plasma (Table 58-1). Potassium is the most abundant intracellular cation, followed by magnesium and a relatively small amount of sodium. The major intracellular anions are organic phosphates and proteins, with smaller concentrations of bicarbonate and sulfate.

The large concentration gradient of electrically charged particles between ECF and ICF is critical to maintaining various cellular functions, such as nerve conductance, muscle movement, and secretory processes. This gradient is maintained by active transport mechanisms found in cell membranes.

The laboratory measurement of serum concentration of electrolytes does not always reflect total body content, and care must be taken when interpreting these results. For example, a shift of intracellular potassium into the intravascular space may lead to a normal serum level while masking a significant decrease in total body content of potassium.

**Figure 58-1** Metabolic requirements of the average hospitalized patient. The center line represents calculated caloric requirements for average hospitalized patients. See text for explanation of the 3 sections of the curve. (Adapted from Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics*. 1957;19(5):823–832.)

Protein	13	55
<b>Total Anions</b>	<b>151</b>	—

## OSMOLALITY AND OSMOTIC PRESSURE

The ICF and ECF are separated from each other by cell membranes that are highly water permeable but selectively impermeable to solutes. The movement of water across the cell membrane is responsible for maintaining osmotic equilibrium. Water will flow along an osmotic gradient from areas of low osmolality to areas of high osmolality, thus maintaining osmotic equilibrium between the ECF and the ICF. Osmolality is a measure of the amount of dissolved solids in the various fluid compartments and is determined by the number of molecules in solution, independent of their size.

By far the most substantial contribution to normal plasma osmolality is made by sodium and its associated anions. Under most circumstances the plasma osmolality is approximately equivalent to twice the concentration of plasma sodium. However, under unusual circumstances, or for precision, the osmolality can be calculated using the following formula:

$$\text{Osmolality} = 2 \times \text{Sodium} + \text{Glucose}/18 + \text{BUN}/2.8$$

Changes in the ECF content of sodium or glucose will cause significant fluid shifts between the ECF and ICF. This shift has important clinical implications, especially in diabetic ketoacidosis, in which hyperglycemia causes a shift of water from the ICF to the ECF and dilutes the plasma sodium (hyponatremia) in spite of an elevated osmolality. In this case, the plasma sodium needs to be corrected for hyperglycemia. The formula for correction is:

$$\text{Corrected sodium} = \text{measured sodium} + [1.6 (\text{glucose} - 100) / 100]$$

Serum sodium concentration falls in proportion to the dilution of the ECF, declining 1.6 mEq/L for every 100 mg/dL (5.55 mmol/L) increment in the plasma glucose level above normal.

Normally, a difference of 10 mOsm/kg exists between the measured and calculated osmolality. This osmolar gap (the result of unmeasured osmoles) should be calculated because it may reflect the presence of unmeasured osmoles such as alcohols (methanol, ethylene glycol, and isopropyl alcohol, or acetone), which often present in toxic ingestions. A mnemonic for some of the more common causes of an elevated osmolar gap is “MAE DIE”: methanol, acetone, ethanol, diuretics (mannitol, sorbitol), isopropanolol, and ethylene glycol. Hypertriglyceridemia (most commonly seen in children with nephrotic syndrome) is another cause of an elevated osmolar gap and should not be overlooked.

## REGULATING TOTAL BODY WATER AND OSMOLALITY

Homeostasis is maintained by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Although the most important determinant of plasma osmolality is sodium, the body maintains normal osmolality not by the regulation of sodium but by the regulation of TBW. Maintaining intravascular fluid volume takes precedence over maintaining osmolality.

## Regulating Osmolality

Normal plasma osmolality is maintained between 275 and 295 mOsm/kg by modification of water intake and excretion. Although some water is produced in the body during oxidation, gastrointestinal (GI) absorption from oral intake is the main source of water. Water loss is primarily regulated via the kidneys and urinary excretion, but other systems play a role, particularly during physiologic states. Evaporative losses through the skin occur with exertion, fever, and increased environmental temperatures. Evaporation also occurs through the lungs with normal breathing, but increases with tachypnea (respiratory illnesses, exertion, or as a compensation for fever). Large losses can occur through the GI tract with infection and inflammatory diseases causing vomiting and diarrhea.

The osmolality in plasma is detected by osmoreceptors in the hypothalamus, which regulate the secretion of antidiuretic hormone (ADH). Thus, during states of elevated plasma osmolality, secretion of ADH is increased, which increases the permeability of the renal collecting ducts to water and maintains normal osmolality by reducing urinary free-water losses. At the same time, a different set of osmoreceptors stimulate the cerebral cortex to facilitate water intake by increasing the sensation of thirst. Healthy adults begin to experience intense thirst at plasma osmolality levels of 290 mOsm/kg, with profoundly increasing intensity as the osmolality reaches 300 to 305 mOsm/kg. At this point, the person consumes large amounts of water (assuming free access, which is not the case with infants and young children) until plasma osmolality is brought back below the thirst-threshold level. The secretion of ADH occurs at a lower threshold than that for thirst and is initiated (thus inhibiting renal water loss) at a plasma osmolality level above 280 mOsm/kg. Similarly a reduction in plasma osmolality leads to the suppression of ADH, increased urinary water loss, and simultaneous suppression of the thirst mechanism.

## Sodium and Sodium Homeostasis

Plasma sodium is the single most important determinant of intravascular volume. Sodium homeostasis depends on the ability of the kidneys to alter its excretion in the urine, which occurs in response to change in effective circulating volume and circulating levels of plasma sodium.

Sodium is the major osmotically active cation in plasma. The total body content of sodium approximates 60 mEq/kg, but almost 43% of this content is contained in bone, most of which plays almost no role in the daily regulation of sodium concentration. Most of the remainder is concentrated in the interstitial and plasma fractions, with only a small amount in the intracellular space.

Sodium homeostasis results from the balance of sodium intake and excretion. Intake is controlled by dietary habits, and although some central regulation for sodium exists given that thirst is present (many patients who lose salt seem to develop a craving for sodium), it seems to be poorly developed and has not yet been localized. The typical American adult's diet contains 100 to 170 mEq of sodium per day; the amount of sodium in an infant's diet varies according

to the amount and composition of formula or human milk the infant receives. Most of the dietary sodium is absorbed actively in the jejunum. Aldosterone secretion increases GI sodium absorption.

Sodium excretion is controlled primarily by the kidneys but also by the GI tract and skin. Although a large amount of sodium is presented to the kidneys during glomerular filtration, almost 99% of it is resorbed in the kidney tubules. In conditions of severe sodium depletion, volume depletion, or both, the amount resorbed may increase to nearly 100%; in cases of sodium and water overload, it may decrease to approximately 90%. The renin-angiotensin-aldosterone system, when stimulated by decreased renal blood flow, facilitates a greater degree of sodium resorption in the distal convoluted tubules and collecting ducts through the action of aldosterone increasing the number of open sodium channels at these sites.

Hyponatremia (serum sodium  $>145$  mEq/L) is often seen in dehydration if the loss of water is greater than that of sodium. These losses may occur through the lungs, skin, stool, or urine (especially in the presence of diabetes insipidus). Another important, although uncommon, cause of hyponatremia in young children is the overuse of commercial enema preparations containing high concentrations of phosphate and sodium. Although elevated sodium content of human milk has been implicated as a cause of hyponatremia in breastfed infants, routine analysis of breast milk composition is unnecessary unless more common causes, such as inadequate milk volume, have been ruled out.

The signs and symptoms of hypernatremic dehydration may be difficult to interpret accurately, and the severity of dehydration may not be apparent based on physical examination alone. ECF volume remains relatively well preserved because of the shift of water from the ICF caused by a change in plasma osmolality; therefore, clinical signs of dehydration are often absent. Hypernatremia results in marked changes in central nervous system function, especially if the electrolyte disturbance occurs rapidly (within a few hours), which is common in small children. Affected infants exhibit marked irritability alternating with severe lethargy. Seizures may occur and may be followed by coma if the condition is not diagnosed and adequate therapy is not initiated. Brain hemorrhage can occur because of the movement of water from the brain cells as subsequent loss of volume in the brain increases the subdural space, which results in tearing of the bridging veins. If the state of hypernatremia persists, then the brain cells react by increasing their intracellular concentrations of osmotically active solutes (previously referred to as *idiogenic osmoles*) glutamate, glutamine, taurine, and the carbohydrate myoinositol. This action reduces neuronal dehydration and has important clinical implications. Rapid correction (ie, reduction of plasma sodium) leads to a shift of free water to the ICF (mainly neurons), leading to cerebral edema, which produces seizures and coma. Thus, carefully lowering the serum sodium level by no more than 10 to 12 mEq/L over a period of 24 hours with frequent monitoring is important. In addition, elevation of the serum sodium concentration may lead to

skeletal muscle rigidity and hyperactive deep-tendon reflexes.

Hyponatremia (serum sodium  $<130$  mEq/L) occurs whenever body sodium stores are diluted or depleted. It is more often related to failure to excrete adequate amounts of water than to simple overhydration; however, in small infants the intake of hypotonic formulas or human milk low in sodium may lower the plasma sodium concentration substantially. Hyponatremic dehydration is less common in children with acute diarrhea and is most often encountered because large stool losses are replaced with solutions containing little or no sodium (eg, water, fruit juices, and colas). Any situation that increases the secretion of ADH may be associated with low serum sodium concentrations. This circumstance is seen in patients who have the syndrome of inappropriate ADH secretion resulting from central nervous system disease, pneumonia, or meningitis. Addison disease and congenital adrenal hyperplasia are associated with excessive loss of sodium in the urine and with retention of potassium. Children who have obstructive uropathy and progressive renal failure are less able to resorb sodium from their renal tubules; therefore, they sustain large sodium losses and may exhibit mild dehydration with a borderline or low serum sodium concentration. Children treated with vasopressin or 1-deamino-8-D-arginine vasopressin may develop iatrogenic hyponatremia, as may children receiving diuretic therapy. The administration of enemas low in saline concentration also may result in hyponatremia. An excessive loss of sodium and water occurs in individuals suffering from heat-related illnesses. The serum sodium concentration reported by the laboratory may be artificially low in the presence of marked hyperlipidemia and hyperproteinemia (pseudohyponatremia). Highly elevated concentrations of blood glucose (as in diabetic ketoacidosis) are associated with real and factitious hyponatremia.

Signs and symptoms of hyponatremia are related to the duration of the lowered serum sodium concentration, the rate of decrease in serum sodium, and the plasma volume status. They are directly related to shifting solute concentrations between the intracellular and extracellular space, and symptoms can be particularly severe if the sodium drop is acute. Hyponatremia associated with diminished plasma volume results in anorexia, muscle cramps, lethargy, and shortness of breath on exertion. With further decreases in sodium concentration, nausea, emesis, and muscle weakness ensue, which may proceed to delirium and seizures. Hyponatremia associated with acute water intoxication is more likely to result in seizures and coma than in conditions in which the plasma volume remains unchanged.

### Potassium

Potassium is the major intracellular cation. The total potassium content is approximately 50 mEq/kg of body weight, with concentrations of intracellular and extracellular potassium of 145 mEq/L and 4 to 5 mEq/L, respectively.

The kidney is the primary organ involved in potassium homeostasis. Potassium is filtered by the glomerulus

and is resorbed and secreted by the tubule. Most potassium absorption occurs in the proximal portions of the GI tract, where it is excreted in the colon in exchange for sodium. Thus, disorders of the kidneys and altered absorption in the GI tract are associated with significant abnormalities in serum potassium levels. Aldosterone is intimately involved in regulating potassium by increasing its excretion from the GI tract, the skin (skin losses are relatively minimal except in patients with cystic fibrosis), and the kidneys. The urinary excretion of potassium results from tubular secretion rather than glomerular filtration. Aldosterone acts at the level of the distal tubule to foster sodium resorption and potassium secretion. Thus, sustained hypovolemic states result in enhanced renal potassium losses. Other examples of renal losses of potassium include renal tubular acidosis (RTA) types I and II, diuretic abuse, and some chemotherapeutics.

Potassium often shifts between the intracellular and extracellular spaces, mediated mostly by alterations in the serum acid-base status. Extracellular potassium concentration increases with systemic acidosis, and alkalosis leads to the movement of potassium into the cell. Other causes of increased cellular potassium uptake include increased insulin activity and  $\beta$ -agonists (albuterol, epinephrine, and dopamine). GI losses are primarily a result of diarrhea and vomiting, but iatrogenic losses occur with nasogastric and gastric tube drainage.

Though relatively uncommon in healthy children, common causes of hyperkalemia are rhabdomyolysis from crush injuries, tumor lysis syndrome, and kidney disease. Acute kidney injury, often present with these conditions, exacerbates hyperkalemia by reducing urinary excretion. Increased potassium levels can be life threatening because of the effect on membrane potential, especially in cardiac muscle. The earliest sign of cardiac toxicity is in the form of tall, peaked T waves (with normal or short QT interval and short PR interval). They are seen at serum concentrations of 5.5 to 6.5 mEq/L. A widened QRS complex with a prolonged PR interval is seen at levels between 6.5 and 7.5 mEq/L. Subsequent increases in serum potassium levels are associated with broad P waves, QT prolongation (7.0–8.0 mEq/L), and absent P waves with a markedly widened QRS (sine wave pattern) at levels above 8.0 mEq/L.

Most patients with hypokalemia are asymptomatic, particularly if the disorder is mild (3.0–3.5 mEq/L). Most commonly the clinical findings in patients with hypokalemia include muscle weakness and ileus. Cardiac effects may also be exhibited on the electrocardiogram by low voltage, flattening of the T waves, depression of ST segments, prominence of U waves, arrhythmias, and asystole. However, these effects are usually not seen until the serum potassium concentration falls below 2.0 mEq/L. When levels fall below 2.0 mEq/L, an ascending paralysis can develop, with eventual respiratory muscle paralysis. The likelihood of symptoms caused by hypokalemia depend on the rapidity of decrease and presence of underlying heart disease; these children should be treated promptly (especially children who are receiving digitalis derivatives).

### Other Ions

Concentrations of chloride, calcium, magnesium, and phosphorous are also critical to the maintenance of cellular function, but their role in typical fluid disturbances is relatively minor and are not discussed here. The remaining ion of interest is bicarbonate, which is crucial to the acid-base buffering system in plasma that is responsible for the close maintenance of a normal pH in the setting of widely varying conditions. Control of the bicarbonate concentration is the result of interactions between its plasma concentration and those of carbon dioxide and water. The concentrations of these components, and thus control and maintenance of pH, are affected by the function of the kidneys and the lungs. In metabolic acidosis, when plasma pH falls in the setting of poor tissue perfusion or increased acid production, the kidney retains bicarbonate ions, whereas the lungs increase their elimination of carbon dioxide by increasing minute ventilation, driving the system toward a higher pH. In respiratory acidosis, usually induced by excessive carbon dioxide production or inadequate elimination by the lungs, the kidney responds by retaining bicarbonate ions. Conversely, with respiratory alkalosis, as in the case of increased minute ventilation and excessive carbon dioxide losses, the kidney excretes increased amounts of bicarbonate ion, lowering plasma pH. A series of conditions that result in the dysregulation of bicarbonate in the kidney are the 4 different forms of RTA. Particularly severe are type 2 RTA and Fanconi anemia, which affect primarily the proximal tubule of the kidney and inhibit bicarbonate resorption. This results in severe acidosis, which the body is unable to correct.

In most situations requiring fluid therapy, a metabolic acidosis prevails as a result of diminished tissue perfusion. Attention to the pH and buffering characteristics of fluids administered is important, but more important is administering sufficient amounts of isotonic fluids that will result in the rapid reexpansion of the ECF. The resulting enhanced tissue perfusion, elimination of tissue acids, and restoration of end-organ function halts the acidosis.

### MAINTENANCE REQUIREMENTS

In clinical practice, maintenance fluids and electrolytes must be provided, and deficits caused by ongoing losses, if any, must be corrected. The key to understanding maintenance fluid and electrolyte requirements is recognizing that they stem from basal metabolism. Metabolism creates 2 byproducts—heat and solute—that need to be eliminated to maintain homeostasis. Heat is lost through insensible evaporation of water from the skin (accounting for two-thirds of insensible water loss; approximately 30 mL/100 kcal) and from the respiratory system (accounting for one-third of insensible water loss; approximately 15 mL/100 kcal). Sensible water losses occur primarily through urine output (55 mL/100 kcal), which is needed by the body to excrete the daily solute byproducts from metabolism. Obligate urine output, the minimal amount of urine needed to eliminate daily solute by-products, is approximately 25 mL/100 kcal.

### Water

Daily water needs are based on insensible losses from the respiratory tract and skin and sensible losses from the

urine and stool. Traditionally, water requirements have been calculated by 1 of 3 methods: body weight, body surface area, or metabolic rate. The water need per unit of body weight changes dramatically with age and size and therefore is not very useful. Body surface area was once thought to correlate well with both metabolic expenditure and fluid needs, but this has been shown not to be the case, especially in neonates and in children between 6 months and 3 years of age. Additionally, surface area is determined by comparing height and weight with a nomogram, which is cumbersome and depends on accurate measurements (height is notoriously difficult to measure in young children and infants). The use of the metabolic rate to calculate fluid requirements is attractive because it is based on physiologic principles and is a constant number; approximately 100 mL (1 dL) of water is needed for every 100 calories consumed. Using an average hospitalized child who has a metabolic rate midway between normal activity and basal metabolic rate as a standard, a fluid requirement can be derived based on calorie expenditure that is quite simple and can be calculated from body weight (Figure 58-2). This value results in a maintenance water requirement of 100 mL/kg per day for each of the first 10 kg, 50 mL/kg per day for each additional kilogram from 11 to 20, and 20 mL/kg per day for each subsequent kilogram. When converting to an hourly fluid rate, the simplest approximation is 4 mL/kg per hour for the first 10 kg, 2 mL/kg per hour for the next 10 kg, and 1 mL/kg per hour for each additional kilogram. This value results, for example, in an hourly maintenance rate of 32 mL/h for an 8-kg infant ( $4 \text{ mL/kg} \times 8 \text{ kg}$ ), 50 mL/h for a 15-kg toddler ( $4 \text{ mL/kg} \times 10 \text{ kg} = 40 \text{ mL}$ , plus  $2 \text{ mL/kg} \times 5 \text{ kg} = 10 \text{ mL}$ ), and 70 mL/h for a 30-kg child ( $4 \text{ mL/kg} \times 10 \text{ kg} = 40 \text{ mL}$ , plus  $2 \text{ mL/kg} \times 10 \text{ kg} = 20 \text{ mL}$ , plus  $1 \text{ mL/kg} \times 10 \text{ kg} = 10 \text{ mL}$ ) (Table 58-2). This simple approach meets the maintenance fluid requirements for most children and should be adjusted up or down depending on factors such as rate of insensible fluid losses (tachypnea, burns) or decreased fluid excretion (renal failure).

### Electrolytes

The maintenance requirement of sodium for the average infant is between 2 and 3 mEq/100 cal, and the

potassium requirement is closer to 2 mEq/100 cal. Because sodium and potassium are supplied routinely in the form of chloride salt, the infant or child receives between 4 and 5 mEq/100 cal of chloride ion, although the absolute chloride requirement probably is very small. An important point to remember is that the amounts of water and electrolytes for maintenance needs are based on the metabolic rate and not body weight. This point is especially important while calculating electrolyte needs in an older child or adolescent.

### Calories

The nutritional component of maintenance therapy should provide a substrate for metabolism. Although optimal nutritional therapy provides an equal number of calories to those expended, for short-term administration of parenteral fluids, little consideration is usually given to replacing caloric expenditure calorie per calorie. Rather, the reason for adding calories in the form of dextrose to parenteral fluids is to prevent ketosis and the breakdown of endogenous protein. This can be accomplished using 5% dextrose containing fluids, which provide between 17 and 20 calories per 100 calories expended. For infants and small children, the absolute glucose requirement to prevent ketosis and overt hypoglycemia is higher (4–6 mg glucose/kg per minute), and these patients may require higher dextrose concentrations.

## COMPOSITION OF MAINTENANCE FLUID FOR PARENTERAL USE

The composition of the parenteral fluid that can be administered under normal circumstances to a hospitalized patient for a short period (up to several days) is calculated based on 1 dL water, 2 to 3 mEq sodium, 2 mEq potassium, and 5 g glucose for every 100 calories expended. The composition of a suitable fluid for maintenance therapy, therefore, would be 20 to 30 mEq sodium, 20 mEq potassium, and 50 g glucose (values expressed per liter) for every 100 calories expended. Values of sodium in parenteral fluids usually are expressed as a fraction of normal saline solution. Normal saline is a 0.9% solution of sodium chloride that provides 154 mEq of sodium per liter of solution. While this calculation would prescribe the use of a quarter-normal

**Figure 58-2** Fluid compartments of the body.

**Table 58-2**

**Holliday-Segar Formula for Determining Daily Maintenance Fluid Requirements**

WEIGHT (kg)	kcal/d OR mL/d	kcal/h OR mL/h
0–10	100 kg/d	4 mL/kg/h
11–20	$1000 + (50/\text{kg/d})^a$	$40 + (2 \text{ kg/h})$
>20	$1500 + (20/\text{kg/d})^b$	$60 + (1 \text{ kg/h})$

<sup>a</sup>For each kg >10.

<sup>b</sup>For each kg >20.

From Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics*. 1957;19(5):823–832.

saline solution (0.225% sodium chloride containing 38 mEq of sodium per liter), evidence has shown that hypotonic maintenance solutions place hospitalized children at high risk for developing hyponatremia, due in most part to high circulating ADH levels as a result of the stresses of illness. Isotonic parenteral solution (normal saline) or at the very minimum, half-normal saline (77 mEq of sodium per liter) has been recommended for use in maintenance fluid therapy, because it has been shown to significantly decrease the risk of developing hyponatremia. Concerns of inducing hyponatremia by using solutions with up to 5 times the physiologic requirement of sodium, have not been borne out in clinical practice. These solutions are usually formulated with 5% glucose (50 g/L); 20 mEq of potassium can be added to each liter, yielding solutions with a higher osmolality than that of plasma, but this effect is transient and dissipates as glucose is taken up by the cells.

### ADMINISTRATION

Once the appropriate concentration of each solute in the parenteral fluid has been determined, the solution is administered through a peripheral vein at a rate of 100 mL/100 cal of the expected energy expenditure. Procedures for gaining vascular access in children are described in Appendix B, Outpatient Procedures. Although not a new method, the technique of administering fluids and medications into the bone marrow (intraosseous infusion) has been demonstrated to be safe and effective in providing volume replacement and resuscitation drugs in an emergency. It may be used in infants and children when intravenous access cannot be obtained rapidly. Techniques for performing this procedure also are found in Appendix B. Any solution that can be given intravenously may be given via the intraosseous route.

### WHEN MAINTENANCE IS NOT ADEQUATE

In the preceding sections, a rational approach is outlined for supplying children with maintenance fluids. Based on the physiologic mechanism of the illness, the needs of any given child may differ considerably from these maintenance requirements. However, the calculations presented remain valid over a wide range of situations if used as a basis on which unusual losses are added. Any and all of the organs normally involved in water homeostasis may be sought as sources or reasons for water loss: water lost through the GI tract in the form of diarrhea or vomiting; massive renal excretion of water in diabetes mellitus or diabetes insipidus, RTA, or after administration of osmotic or other diuretics; excessive sweating caused by autonomic instability, fever, or high ambient temperature; and an increased loss of lung water with hyperpnea from any cause, including hyperpyrexia. Processes that do not normally contribute to water loss also may be involved, such as losses through a nasogastric tube and acute blood loss. In addition, increased demands for fluids exist in various conditions of elevated metabolic rate (eg, thyrotoxicosis), in situations that create

large shifts in the body's fluid compartments (usually of the vascular space), and in many perioperative conditions (third spacing) that, if uncorrected, may produce shock. The persistence of any of these abnormal conditions in the absence of adequate fluid intake leads to water or electrolyte deficits or both. In addition, the fluid administration scheme must take into consideration ongoing losses and provide appropriate replacement of these lost fluids.

Fluids sometimes need to be supplied in amounts below those estimated for the average hospitalized patient. Any child who has a diminished urine output because of renal failure or acute kidney injury may not require as much free water as the child's healthy counterpart. Children who are placed in mist tents or maintained on ventilators lose less water through their lungs and should have a lower estimate made of insensible water loss. Children whose activity levels are below those predicted for most bedridden patients (eg, those in coma or who are paralyzed) expend fewer calories and therefore require less water (Figure 58-2).

### ESTIMATING AND CORRECTING DEFICITS AND ONGOING LOSSES

The best way to estimate fluid and electrolyte deficits is to determine how much fluid has been lost from each body compartment, the electrolyte concentration of the lost fluid, and the period over which such losses have occurred. In most situations, however, therapy must be initiated before these data can be collected. In addition, the volumes of diarrheal or emetic losses may be extremely difficult to measure.

The first step in evaluating a child who has a fluid and electrolyte deficit is to determine the degree of total body volume that has been lost. Although fluids and electrolytes are lost from all body compartments, the intravascular volume status is the most immediately relevant. Children who have sustained severe losses of intravascular (circulating) fluid volume are at risk for shock, which may result in irreversible organ system damage and death if not addressed promptly.

Table 58-3 contains a systematic approach to estimating fluid losses. Typically, a child may be categorized as mildly, moderately, or severely dehydrated according to clinical findings. (The term *dehydration* is used here in its most common sense, meaning losses of fluid volume. Technically, dehydration refers only to pure water losses, a condition almost never seen clinically.) Attention should be given to the immediate replacement of the estimated fluid losses via the oral (including nasogastric administration), intravenous, or intraosseous routes, depending on the child's overall clinical status. Even before a formal calculation is made, an initial fluid bolus of 20 mL/kg over 20 to 30 minutes should be given to any child who seems to be severely dehydrated or in shock.

When calculating the final amount of fluid to be replaced, either a recent normal weight should be used, if available, or the deficit may be calculated based on an average (50th percentile) weight for the child's age. Formerly, fluid replacements were administered over a 24-hour period, with the aim of restoring one-half of

**Table 58-3** Signs and Symptoms Related to Degree of Dehydration<sup>a</sup>

PARAMETER	DEGREE OF DEHYDRATION		
	MILD	MODERATE	SEVERE
Weight loss in child <1 y (%)	3–5	10	15
Weight loss in patient >1 y (%)	2–3	6–9	>10
Skin color	Pale	Gray	Mottled
Skin turgor	May be normal	Decreased	Tenting
Mucous membranes	Slightly dry	Dry	Dry, parched, collapse of sublingual veins
Eyes	Probably normal	Decreased tears	Sunken, absence of tears, soft globes
Central nervous system	Normal	Irritable	Lethargic
<b>PULSE</b>			
Quality	Strong	Somewhat decreased	Distal pulse not palpable
Rate	Probably normal	Somewhat increased (orthostatic changes)	Markedly tachycardic
<b>OTHER PARAMETERS</b>			
Capillary refill	Normal (<2 s)	2–4 s	>4 s
Blood pressure	No change	Orthostatic decrease	Decreased while supine
Urine	Probably normal or slightly decreased volume	Elevated specific gravity, decreased volume	Less than 0.5 mL/kg/hr over the previous 12–24 hr; may be anuric

<sup>a</sup>Table is most useful for situations involving isotonic dehydration. (See text for adjustments needed for other forms of dehydration.)

the deficit in the first 8 hours of therapy and the second half in the subsequent 16 hours. It is apparent that faster rates of fluid repletion are both more effective and simpler and that complicated formulas for calculating fluid and electrolyte replacements are not necessary. In most cases, dehydration of a mild to moderate degree may be managed on an outpatient basis, often without the use of intravenous therapy. In general, the aim should be to replace the entire calculated deficit in the initial 4 to 6 hours of treatment. This more rapid treatment hastens the restoration of circulating fluid volume, speeds the excretion of tissue acids and ketones that are the result of diminished end-organ perfusion, and contributes to the more rapid resolution of compensatory mechanisms such as renal sodium retention and potassium losses.

In the vast majority of cases, electrolyte determinations do not add useful information to management. The exceptions to this rule include a child who has a severely abnormal mental status (irritable or lethargic), seizures, or clinical signs of hyponatremia or hypernatremia. Furthermore, normal saline should be the initial fluid of choice in virtually all instances, until a specific electrolyte abnormality is detected that mandates a more hypertonic or hypotonic solution. Regardless of the measured serum sodium concentration, a child who is significantly dehydrated usually has a net deficit of *total body sodium*; thus, even a hypernatremic child (as determined by the serum concentration of sodium) will benefit from the initial administration of normal saline.

The fluid volume for an initial rehydration should be based on calculated or estimated healthy weight. After an initial bolus administration of 20 mL/kg over 20 to 30 minutes, the child should be re-evaluated. If evidence of shock persists, then repeated boluses should

be administered, with re-evaluation after each bolus. When heart rate and capillary refill times have returned to normal, the rate of fluid administration may be reduced to an amount calculated to replace the remaining deficit over 4 to 6 hours. In a healthy child who has normal kidneys, this task usually may be accomplished safely by administering half-normal saline (77 mEq of sodium per liter).

### THERAPEUTIC APPROACH TO SHOCK

A severe plasma volume deficit, with actual or impending cardiovascular collapse, is a life-threatening pediatric emergency requiring *immediate* action. Initial therapy replaces the intravascular volume depletion with normal (0.9%) saline. (See Chapter 373, Shock.) Hemorrhagic shock, which must be considered with any history of trauma or any possible internal source of bleeding (eg, a known peptic ulcer or other GI disease that might lead to acute blood loss), must be treated with the administration of packed red blood cells. This treatment is required because administering additional electrolyte solutions to a patient who has an already diminished hematocrit decreases oxygen-carrying capacity further and may result in irreversible damage to vital organs (especially the heart and brain). Therefore, most hospital blood banks keep a ready supply of type O blood, which should be infused as rapidly as possible once the diagnosis of hemorrhagic shock has been considered. A sample of the patient's blood (obtained before transfusion) should be sent to the blood bank so that a properly matched unit of donor blood can be obtained without delay in case it is needed for further therapy. In addition, if the patient's blood type is known, then type-specific non-cross-matched blood, which carries less risk than the use of type O non-cross-matched

blood, may be administered. While awaiting the arrival of blood from the blood bank, normal saline solution should be given. The use of colloid-containing plasma expanders such as albumin or dextran remains controversial and probably provides no benefit over the use of a crystalloid solution unless the shock is the result of protein loss. In addition, if the shock is cardiogenic, then administration of albumin may worsen pulmonary edema. In sepsis, in which volume depletion is caused by leaky capillaries and the exudation of plasma into the extravascular spaces, fresh-frozen plasma may be useful (because it also replaces many clotting factors) and is sometimes used in combination with other fluids. In infants and small children, shock is associated almost invariably with the depletion of glycogen stores. Thus, hypoglycemia often may be present. The administration of 2 to 4 mL/kg of a 25% dextrose solution corrects hypoglycemia and improves the results of further resuscitation efforts. For this reason, rapid bedside determination of blood glucose concentration should always be a part of the initial evaluation of the infant or child in shock (current or impending).

## SERIOUS ELECTROLYTE ABNORMALITIES

Although most patients who are dehydrated may be given the empirical administration of normal saline, and without the measurement of serum electrolytes, in special situations more attention must be given to electrolyte status. Clinically, these situations will become apparent if a child demonstrates signs associated with hypernatremia or hyponatremia or if signs of dehydration do not resolve in response to standard management. This section examines specific electrolyte abnormalities.

### Sodium

The pediatric electrolyte aberrations encountered most commonly relate to sodium balance, and they ordinarily occur with dehydration. When a significant electrolyte disturbance is evident, efforts must be made to determine the cause of the disturbance and any factors that may tend to perpetuate it, so that they can be addressed in the treatment plan.

### Hyponatremia

Hyponatremia is usually associated with hypotonicity. When it is not, the physician must suspect either an artifactual lowering of serum sodium, such as with hyperlipidemia and hyperproteinemia, or the presence of an osmotically active substance such as glucose or mannitol. These compounds cause a shift of intracellular water into the extracellular space to restore osmotic neutrality, thereby lowering effective serum sodium by 1.6 mEq/L for every 100 mg/dL rise in serum glucose or mannitol concentration. Such situations are associated almost universally with the preservation of intravascular volume (except in some extreme cases of diabetic ketoacidosis) and are often apparent from the history, physical examination, or a few simple laboratory tests. Table 58-4 summarizes the causes of hyponatremia. The clinical manifestations of hyponatremia are primarily neurologic and are related

**Table 58-4**

**Causes of Hyponatremia**

TYPE	CAUSE
Pseudohyponatremia (Hyperosmolality)	Hyperglycemia
Hypovolemic hyponatremia	Mannitol
	• Gastrointestinal losses (vomiting, diarrhea)
	• Excessive sweating
	• Renal losses (diuretics, urinary obstruction, salt-wasting nephropathy, etc)
Euvolemic hyponatremia	• Syndrome of inappropriate secretion of antidiuretic hormone
	• Glucocorticoid deficiency
	• Water intoxication (excessive hypotonic intravenous fluids)
	• Child abuse, tap water enemas, psychogenic polydipsia
Hypervolemic hyponatremia	• Congestive cardiac failure
	• Cirrhosis
	• Nephrotic syndrome

to cerebral edema caused by hypo-osmolality. These manifestations occur in the form of headaches, nausea, vomiting, and weakness. As the cerebral edema worsens, patients develop behavioral changes and impaired response to verbal and tactile stimuli.

The most common clinical situation leading to hyponatremia is volume loss. This is usually caused by diarrhea and subsequent volume depletion, which causes a nonosmotic release of ADH. This ADH release increases resorption of free water but not sodium in the kidney, thereby lowering serum sodium levels. If ongoing diarrheal losses are replaced with hypotonic fluids, then hyponatremia will develop, even if the volume deficit is not great. Abnormal accumulations of isotonic fluid from the intravascular space into other body cavities (such as in ascites) is known as *third spacing*. This intravascular volume loss also stimulates ADH release and subsequent free-water resorption and development of hyponatremia.

When volume status is normal, the physician must consider situations that lead to a combination of sodium loss with water intake sufficient to maintain usual hydration. Such a negative sodium balance can result from severe restriction of sodium intake or profound loss of sodium through the skin (cystic fibrosis), GI tract, or kidneys (salt-losing nephropathy or diuretic use).

Mild hyponatremia (serum sodium 128–134 mEq/dL) with normovolemia or hypovolemia is usually undetectable clinically and can be managed by providing isotonic sodium solutions with adequate fluid administration, thereby allowing the excretion of water at an appropriate rate. When simultaneous large deficits of both water and sodium occur, both must be replaced effectively; the usual normal saline solution is sufficient at the outset.

Severe total body potassium depletion, sometimes overlooked, may lead to persistent hyponatremia. Because potassium is the major intracellular cation,

sodium ions enter the cells to replace potassium ions to provide electroneutrality; therefore the concentration of sodium in the extracellular space may fall. Potassium then must be supplied to restore normal sodium balance.

More rapid correction of the sodium deficit may be necessary with serious symptoms (seizures), which may accompany a large or precipitous decline in serum sodium concentration. Rapid correction can be achieved through the administration of 3% saline solution (containing 500 mEq of sodium per liter), which allows rapid replacement of sodium without infusing a large volume of water. The administration of 4 to 6 mL/kg of 3% saline over 1 hour, or alternatively 2 mL/kg boluses of 3% saline (up to 100 mL) over 10 minutes and repeated 1 to 2 times based on response, provides rapid and temporary relief of signs of severe hyponatremia. This temporary relief is achieved by serum sodium level elevations of 4 to 6 mEq/L, thereby reducing cerebral edema. Osmotic equilibrium is established rapidly once intravascular tonicity is restored, because sodium is distributed quickly throughout all body fluid compartments. The intravenous administration of hypertonic sodium chloride solutions is not without risk to the patient, however, especially a patient who has cardiac or renal disease. Such infusions cause a rapid shift of water into the intravascular space and may lead to acute volume overload. This therapy must therefore be reserved for potentially life-threatening situations, and the child must be monitored closely throughout the infusion. Demyelination syndromes have been noted in adults because of the rapid reversal (a rise of more than 12 mEq/L in 24 hours) of long-standing or chronic hyponatremia.

When hyponatremia exists with *expanded* vascular volume, the most likely cause is excessive secretion of ADH, which may occur because of increased intracranial pressure, severe pneumonia, or the stress of certain surgical procedures. Syndrome of inappropriate secretion of ADH (SADH) is diagnosed based on laboratory and physical examination data and requires the presence of hyponatremia with normal or increased intravascular volume. In patients with SADH, sodium excretion in the urine is variable but is usually higher than expected for the level of serum sodium concentration. Treatment of this disorder, whatever the cause, consists of fluid restriction and no sodium administration, unless the patient is convulsing. If fluids must be given, they should be isotonic, with hypertonic fluids for seizures. Concurrent administration of furosemide or other potent diuretics with hypertonic solutions to increase free water diuresis should be avoided unless there is impending heart failure from volume overload, because of an increased risk of hypotension. Some authors, however, have endorsed the use of desmopressin with 3% sodium chloride administration to correct severe, symptomatic hyponatremia. In most cases, however, fluid restriction remains the safest and most efficacious mode of therapy. Once the sodium concentration returns to near normal, moderate fluid restriction (generally to two-thirds of maintenance requirements) may need to be continued, usually for at least 24 hours but sometimes for as long as the underlying disorder persists.

### Hypernatremia

As with decreased serum sodium concentration, hypernatremia may occur with overhydration, dehydration, or normal hydration. However, unlike hyponatremia, an elevated serum sodium level is *always* associated with hypertonicity. Table 58-5 summarizes the causes of hypernatremia.

Hypernatremia associated with overhydration is generally an iatrogenic problem created by administering intravenous or oral solutions with high salt content and failing to provide the requisite free water. Patients treated with large amounts of sodium bicarbonate for metabolic acidosis are also at risk of developing marked hypernatremia (approximately 1 mEq of sodium is administered for every milliliter of bicarbonate solution). Occasionally, when infant formulas are being mixed, mistakes occur, which result in markedly hypertonic solutions that may induce particularly severe hypernatremias. These patients are at risk of developing obvious signs of plasma volume overload, including hypertension, congestive heart failure, and pulmonary edema. Under such circumstances, administering additional fluid is risky and may prove fatal. The most rational approach is to limit sodium and water intake and to attempt to induce sodium loss to a greater extent than water. This task may be accomplished by using a potent loop diuretic such as furosemide, which induces a net sodium loss if the child's renal function is adequate. Concurrently, the physician must watch closely for the development of dehydration, because predicting precisely how much water and sodium will be lost is impossible. Generally, some portion of the induced urine output (50%–75%) should be replaced with intravenous fluid that is slightly hypotonic (ie, 66% or 75% normal saline solution) until normal hydration and tonicity have been achieved. In patients who have severe hypernatremia (ordinarily considered as a serum sodium value >160 mEq/L), serious complications may occur if the sodium concentration falls too rapidly. This action produces marked shifts of extracellular water to the intracellular space and results in cellular swelling. This swelling is most

**Table 58-5**

**Causes of Hypernatremia**

MECHANISM	CAUSE
Excessive sodium	<ul style="list-style-type: none"> <li>• Improperly mixed formula</li> <li>• Intentional (Munchausen syndrome by proxy)</li> <li>• Hyperaldosteronism</li> </ul>
Water deficit	<ul style="list-style-type: none"> <li>• Nephrogenic diabetes insipidus</li> <li>• Central diabetes insipidus</li> <li>• Increased insensible losses (prematurity, phototherapy)</li> </ul>
Water and sodium deficits	<ul style="list-style-type: none"> <li>• Gastrointestinal losses (diarrhea, nasogastric suction)</li> <li>• Skin losses (burns, excessive sweating)</li> <li>• Renal losses (osmotic diuretics, diabetes mellitus)</li> </ul>

worrisome in the central nervous system because of the potential for cerebral edema, which may lead to seizures, coma, or death. Therefore, when the serum sodium value is high and is accompanied by overhydration, the preferred therapeutic approach is to restrict sodium and water, thus permitting a spontaneous diuresis to occur. Serum electrolyte values must be monitored every few hours. If the patient has substantially decreased renal function, then hemodialysis or peritoneal dialysis should be considered, especially in the presence of hypertension or pulmonary edema.

Hypernatremia associated with decreased plasma volume is often encountered in pediatric practice. It is caused most commonly by acute gastroenteritis that induces relatively larger losses of water than sodium. Although these children may have severe hypernatremia, their total body sodium content is usually depleted; they therefore present a therapeutic challenge. Hypernatremia can be seen in the first few days after birth in breastfed infants because of inadequate breast milk ingestion resulting from either decreased production, inverted nipple, or swallowing problems.

Patients with hypernatremic dehydration need to be evaluated carefully. The physician must consider all the aspects of dehydration previously discussed but must remember that because ECF volume is relatively well preserved, the severity of the plasma volume loss may be seriously underestimated. Even with significant fluid losses, these children rarely have signs of incipient vascular collapse. When using the signs and symptoms of dehydration shown in Table 58-3 to determine the degree of dehydration, if the serum sodium concentration is greater than 155 mEq/L, then another 3% to 5% should be added to the weight loss in predicting the degree of dehydration.

Fluid therapy of hypernatremic dehydration is not nearly as straightforward as for other types of dehydration because of the increased risk of creating major fluid shifts and cerebral edema. The physician cannot simply try to remove sodium, because a decrease in the plasma tonicity without an increase in plasma water may induce circulatory collapse. Therefore a cautious rehydration scheme must be developed.

Instead of being rehydrated over a short period, as with isonatremic or hyponatremic dehydration, the child who has a serum sodium greater than 155 mEq/L should have the fluid deficit replaced over 48 to 72 hours. Calculating the actual amount of sodium lost is *not* possible. The physician should estimate the water deficit (based on weight and clinical signs) and plan to replace this volume evenly over 48 to 72 hours. The solution used should be slightly hyponatremic (containing 100 to 120 mEq of sodium per liter). Glucose should be added so that the solution is not hypotonic. As soon as the urine output is judged to be adequate, potassium should be added to the intravenous solution to correct the potassium deficit and to preserve the intracellular osmolality, thus helping to prevent intracellular edema. Particularly important is to monitor serum electrolyte concentrations, serum osmolality, and urine output and osmolality as frequently as possible. Although the physician needs to avoid a persistent

elevation of the serum sodium concentration, ensuring a slow, steady decline in the serum sodium and osmolality levels is also important. Decreases in serum tonicity should be limited to a rate of 5 mOsm/h. Serum sodium concentration should fall at a rate no more rapid than 0.5 mEq/L/h. In many cases, adding up to 40 mEq of potassium per liter to the infused solution and reducing its sodium concentration to 50 mEq/L is feasible.

Sometimes, no matter how carefully hypernatremia is handled, seizures ensue during the rehydration period. They can usually be managed successfully by infusing a solution slightly more hypertonic than the solution being given (ie, normal saline or lactated Ringer solution). If the seizures are particularly severe, or evidence exists of brain herniation, then a hypertonic agent such as mannitol or 3% saline may be required. Unfortunately, the diuresis induced by mannitol may worsen the dehydration substantially. In addition, mannitol should not be used if urine output has not been established.

A relatively uncommon cause of hypernatremia is diabetes insipidus, which usually leads to hypernatremia with a normal plasma volume. This circumstance presupposes an intact thirst mechanism and that the patient has access to the large volume of water required to replace renal losses, which usually allows them to maintain a normal serum sodium level. Such is not the case for small infants and patients who have diabetes insipidus and hypernatremic dehydration. Large renal losses of free water may occur because of deficient ADH (central or pituitary diabetes insipidus) or impairment of the normal renal response to the hormone (nephrogenic diabetes insipidus).

In infants and children, the most common causes of central diabetes insipidus are inherited familial conditions, histiocytosis and other central nervous system diseases of vascular, infectious, or granulomatous origin. The most common causes in older children and young adults are head trauma and idiopathic causes associated with brain malformations. Across all ages, the syndrome may follow brain tumors and intracranial surgical procedures.

Nephrogenic diabetes insipidus may be evident as a congenital disorder, but it is more commonly caused by renal failure (particularly that caused by obstructive uropathy) or electrolyte disorders, drug ingestions, or sickle cell disease. Laboratory findings in patients with diabetes insipidus usually include a moderate to marked hypernatremia (depending on how adequately the lost fluid volume has been replaced) and dilute urine, usually produced in large volumes. Clinically, these patients exhibit a tremendous thirst (often craving ice-cold water) and usually show signs of normal hydration. The laboratory differentiation between central and nephrogenic diabetes insipidus is unnecessary when the cause is apparent (eg, after surgical removal of a craniopharyngioma) but in other situations is essential to help guide the therapeutic approach. This differentiation is generally determined by performing a water deprivation test in adults and older children (monitored closely in the hospital setting). For infants and young children, desmopressin infusion followed by serial

measurement of urine osmolality replaces the water deprivation test.

## Potassium

### Hypokalemia

A low serum potassium concentration seldom represents an emergency unless cardiac effects are seen, which do not typically occur until the serum potassium level is less than 2 mEq/L. In patients receiving digitalis preparations, however, a combined cardiac toxicity may ensue, and the typical T-wave changes and arrhythmias of hypokalemia may occur at serum potassium levels closer to normal. Other patients at risk of exhibiting an exaggerated response to mild hypokalemia include those who have an acid-base disturbance or other ionic aberration that may create a cardiac conduction disturbance by substantially altering the flux of ions between the intracellular and extracellular spaces. At particular risk of developing such alterations are children receiving long-term diuretic therapy. Hypokalemia may occur after large losses of potassium from the kidneys in children with diabetic ketoacidosis and as a manifestation of hyperaldosteronism. (Table 58-6 lists the causes of hypokalemia.)

When emergency therapy for hypokalemia is necessary (usually in the form of intravenous potassium at a dose of 0.5–1.0 mEq/kg usually given over 1 hour and in the preoperative patient who has a serum potassium concentration <3.5 mEq/L), intravenous potassium repletion should be implemented. This task is accomplished either by increasing the concentration of potassium ion in the fluids given intravenously (maximum of 80 mEq/L) or by administering a bolus of potassium into a central vein. The maximal amount of potassium that may be given is 1 mEq/kg over a 1-hour period (with the physician at the bedside and continuous electrocardiographic monitoring), but it is generally safer to deliver only 20% or 25% of this amount and to repeat the dose as necessary to raise the concentration to a safe level. In nonemergent circumstances, enteral potassium supplementation is safer and very effective.

Table 58-6 Causes of Hypokalemia	
MECHANISM	CAUSE
1. Spurious	High white cell counts
2. Transcellular shifts	<ul style="list-style-type: none"> <li>• Alkalosis</li> <li>• Insulin</li> <li>• <math>\beta</math>-agonists (albuterol), toxins (theophylline)</li> </ul>
3. Decreased intake	—
4. Extrarenal losses	Diarrhea, sweating, laxative abuse
5. Renal losses	<ul style="list-style-type: none"> <li>• With metabolic acidosis (renal tubular acidosis)</li> <li>• Without acid–base imbalance (interstitial nephritis)</li> <li>• With metabolic alkalosis (cystic fibrosis, Bartter syndrome)</li> <li>• With high blood pressure (licorice ingestion, Cushing syndrome)</li> </ul>

### Hyperkalemia

Substantial elevations of serum potassium concentration are encountered most commonly in patients with renal failure or systemic acidosis, combined with an increased intake of potassium or a rapid breakdown of tissue or blood products. Table 58-7 summarizes the causes of hyperkalemia.

The treatment of hyperkalemia should focus on stabilizing cardiac conduction and the heart muscle, facilitating a rapid shift of serum potassium intracellularly to temporarily decrease serum potassium levels, and removing potassium from the body to permanently reduce serum levels.

When the potassium concentration reaches 7 mEq/L or more, or if characteristic electrocardiographic abnormalities are noted at any potassium concentration, then the child is in grave danger of cardiac toxicity. Such a patient should have continuous electrocardiographic monitoring, and immediate steps should be taken to protect the heart from the effects of severe hyperkalemia. The first priority is the infusion of intravenous calcium, 0.2 mL/kg of 10% calcium chloride given over 2 to 5 minutes, which can be repeated at 5-minute intervals.

As a temporizing measure, to decrease serum potassium levels rapidly, steps should be taken to drive the potassium intracellularly. First, a combined insulin and dextrose infusion induces movement of potassium ions from the extracellular to the intracellular spaces. This accelerates the usual process by which glucose moves into the cells and is converted to glycogen. A dose of 2 mL/kg of 25% dextrose solution is given along with 1 U/kg of regular insulin. These may be administered over 30 minutes and repeated as necessary. Serum glucose concentration must be monitored closely during and after therapy. Selective  $\beta$ -2 agonists (salbutamol), are very effective in driving potassium into the cell. They may be administered intravenously or by nebulization. The parenteral form is not yet available.

**Table 58-7 Causes of Hyperkalemia**

MECHANISM	CAUSE
1. Spurious laboratory values	Hemolysis, leukocytosis, faulty blood draw techniques
2. Increased intake	Oral or intravenous, blood transfusion
3. Transcellular shifts	<ul style="list-style-type: none"> <li>• Acidosis</li> <li>• Rhabdomyolysis, tissue necrosis, tumor lysis syndrome</li> <li>• Drug toxicity (<math>\beta</math>-blockers, digitalis)</li> </ul>
4. Decreased excretion	<ul style="list-style-type: none"> <li>• Renal failure</li> <li>• Adrenal (Addison disease, congenital adrenal hyperplasia)</li> <li>• Kidney transplant, lupus nephritis</li> <li>• Renal tubular acidosis (pseudohypoaldosteronism)</li> <li>• Medications (angiotensin-converting enzyme inhibitors)</li> </ul>

commercially in the United States. Sodium bicarbonate (2–3 mEq/kg given within a 30-minute period) to raise the serum pH level and help move the potassium into the cells can be considered, but is extremely controversial and is only recommended in cases of severe acidosis or in patients receiving hemodialysis.

Once lifesaving measures have been instituted, attention must be given to removing potassium from the body. One of the most effective means of accomplishing this task is with hemodialysis or peritoneal dialysis. Either one or the other should be initiated without delay in patients who have hyperkalemia accompanied by congestive heart failure and volume overload. The other mechanism used commonly for removing potassium from the body is to bind potassium in the GI tract by using an exchange resin such as sodium polystyrene sulfonate. This exchange resin is usually introduced through a retention enema that contains sorbitol. The physician can expect a decline in serum potassium of 1 mEq/L for each gram per kilogram of resin introduced. The dose is calculated based on the severity of the hyperkalemia, with a maximal adult dose of 60 g. Caution should be used in patients who have renal failure because sodium is absorbed as potassium is excreted, and each gram of resin contains 4.1 mEq of sodium; hyponatremia and hypervolemia may result. In addition, the patient must be monitored for the development of hypocalcemia and hypomagnesemia. Metabolic alkalosis may result from repeated polystyrene sulfonate enemas. When hyperkalemia becomes a chronic but not life-threatening problem, the best approach is to restrict dietary potassium and administer potassium-losing diuretics concomitantly.

## FLUID THERAPY IN SPECIAL SITUATIONS

### Fluid Therapy in the Neonate

Adequate provision of fluid replacement therapy for newborns depends on perinatal alterations in body composition and the infant's size and gestational age. Hydration of sick premature infants who weigh less than 1,500 g is discussed in Chapter 111, Care of the Sick or Premature Infant Before Transport.

The content of TBW decreases progressively throughout gestation and the first year of postnatal life. This decrease is accompanied by increases in the body's content of protein and fat. The shrinkage of the ECF compartment accounts largely for the decrease in TBW. In the first few days of extrauterine life, both term and premature infants normally lose up to 10% of their body weight. Although this loss is considered a physiologic reduction, failure to replace such losses may lead to substantial dehydration.

All newborns show a progressive increase in their metabolic rate. The metabolic rate for full-term infants approximates 32 cal/kg per day at birth and reaches close to 43 cal/kg per day within 3 days. This progressive increase is followed by a slow, steady increase over the first 2 weeks after birth. Premature infants maintain a higher metabolic rate than full-term infants, even when they achieve a similar weight.

In addition to the baseline metabolic expenditure of calories, newborns use energy with cold, stress, and

muscular activity. The growth rate is rapid during this period, and the average newborn requires between 100 and 125 cal/kg per day.

Water requirements are governed by losses through the skin, respiratory tract, and kidneys. Evaporative losses through the skin generally average 20 to 30 mL/kg per day; respiratory losses account for approximately 15 mL/kg per day. Both parameters are affected by ambient humidity, and respiratory losses may actually be reduced by 50% with provision of high humidity to the infant's immediate environment.

The newborn's kidneys, though having a full complement of nephrons, do not have the same surface area and therefore have less filtering and concentrating ability. Though kidney function continues to mature as the infant ages, this difference in concentration ability requires special attention.

As the solute load increases, the free water requirement rises; thus, for a formula-fed infant, urinary water loss may be as high as 120 mL/kg per day. However, the average range probably is closer to 60 to 75 mL/kg per day.

Electrolyte requirements for infants have not been fully established, but infants seem to tolerate a fairly wide range of electrolyte provisions. Fluids that have been used successfully yield between 1 and 3 mEq of sodium per 100 calories per day; this has become the recommended starting range for maintenance fluid therapy.

When preparing a maintenance parenteral fluid formula for newborns, the pediatrician needs to ensure adequate monitoring, which will indicate whether fluid estimates have been adequate. Also important, especially with the sick neonate, is to record weights once or twice per day and to record intake, output, vital signs, urinary osmolality, electrolyte concentrations, and other indications of optimum cardiac and respiratory homeostasis frequently. Frequent changes may be needed; therefore, the physician must never become locked into a particular formula but rather must apply the basic rules of fluid therapy to the situation logically and be ready to compensate for failing systems or increasing losses when necessary.

### Fluid Therapy for Burns

See Chapter 375, Thermal Injuries, for fluid management of children with burns.

### Hydration of the Ambulatory Patient: Alternatives to Parenteral Fluid Therapy

A fairly common practice for pediatricians in the United States is to recommend oral fluids for young patients who have mild diarrhea or vomiting. Such therapy has been suggested for many years on totally empirical grounds. Most physicians have urged the use of a dilute solution that contains sodium and potassium in concentrations of 30 and 20 mEq/L, respectively, and 5% to 7% glucose. When diarrhea leads to moderate or severe dehydration, or if substantial emesis accompanies the illness, then the standard teaching dictated hospitalization of such children and resting the GI tract with the use of parenteral therapy, as outlined in previous sections.

Sodium absorption in the small intestine depends on the presence of glucose or small neutral amino acids such as glycine or alanine. Similarly, the absorption of glucose is enhanced by the presence of sodium salts, and this mechanism of coupled transport is responsible for the efficacy of the ORS. Movement of salt and glucose across the mucosal border is accompanied by an influx of water and other electrolyte concentrations. Maximal rates of absorption are achieved when sodium and glucose are present in a 1:1 to 1:2 molecular ratio, glucose concentration is between 110 and 140 mmol (2%–2.5% solution), and sodium concentration is not substantially less than that of normal jejunal fluid (usually 12 mEq/L). The World Health Organization (WHO) has derived a formula for use with all patients who have diarrheal illness regardless of its cause. It contains 90 mmol of sodium, 20 mmol of potassium, 30 mmol of bicarbonate, 80 mmol of chloride, and 111 mmol of glucose per liter. This formulation provides a solution that has an osmolality of 331 mOsm/L. When given ad libitum to patients who have diarrhea, this formula corrects dehydration rapidly and can return electrolyte concentrations to the normal range regardless of the presence of hyponatremia or hypernatremia on initial evaluation. Large field studies have documented its successful use in patients who have ongoing emesis. No evidence has been found to suggest that the use of such fluid prolongs

the duration of diarrhea; the reverse seems to be the case. In addition, children given this oral rehydration therapy seem to tolerate resumption of a regular diet earlier than those treated solely with intravenous fluids. Use of a solution that has lower osmolality (224 mOsm/L) has been shown to result in superior water absorption and patient weight gain.

The guidelines for managing mild, moderate, or severe dehydration as recommended by the Centers for Disease Control and Prevention, American Academy of Pediatrics (AAP), and WHO are summarized in Table 58-8.

Preparations that meet WHO and AAP guidelines, as indicated previously, are available commercially. Because such preparations are available ready to use, the bicarbonate found in the WHO powder has been replaced with citrate. Studies have documented the equivalent efficacy of the 2 bases in correcting the mild acidosis that accompanies mild to moderate diarrhea. Most of the large-scale evaluations that have been performed in developed countries have excluded the use of oral rehydration solution (ORS) in patients in shock who are treated initially with intravenous fluids. Despite considerable efforts to develop a super ORS, most evidence suggests that the standard WHO solution, accompanied by early return to normal diet and sufficient access to free water, is still the best overall therapy. Treatment consists of 2 phases: rehydration and maintenance. In the rehydration phase,

**Table 58-8****Summary of Treatment Based on Degree of Dehydration**

DEGREE OF DEHYDRATION	REHYDRATION THERAPY	REPLACEMENT OF LOSSES	NUTRITION
Minimal or no dehydration	Not applicable	<ul style="list-style-type: none"> <li>• &lt;10 kg body weight: 60–120 mL ORS for each diarrheal stool or vomiting episode</li> <li>• &gt;10 kg body weight: 120–240 mL ORS for each diarrheal stool or vomiting episode</li> </ul>	Continue breastfeeding, or resume age-appropriate normal diet after initial hydration, including adequate caloric intake for maintenance <sup>a</sup>
Mild to moderate dehydration	ORS, 50–100 mL/kg body weight over 3–4 h	Same	Same
Severe dehydration	Lactated Ringer solution or normal saline in 20 mL/kg body weight intravenous amounts until perfusion and mental status improvement; then administer 100 mL/kg body weight ORS over 4 h or 5% dextrose half-normal saline intravenously at twice maintenance fluid rates	Same; if unable to drink, administer through nasogastric tube or administer 5% dextrose quarter-normal saline with 20 mEq/L potassium chloride intravenously	Same

ORS, oral rehydration solution.

<sup>a</sup>Overly restricted diets should be avoided during acute diarrheal episodes. Breastfed infants should continue to nurse ad libitum even during acute rehydration. Infants too weak to eat can be given breast milk or formula through a nasogastric tube. Lactose-containing formulas are usually well tolerated. If lactose malabsorption seems clinically substantial, then lactose-free formulas can be used. Complex carbohydrates, fresh fruits, lean meats, yogurt, and vegetables are all recommended. Carbonated drinks or commercial juices with a high concentration of simple carbohydrates should be avoided. From Centers for Disease Control and Prevention, Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy for the Centers for Disease Control and Prevention. *MMWR Recomm Rep.* 2003;52:1–16.

fluid deficit is replaced quickly, whereas in the maintenance phase, calories are added along with fluids. The intent of this therapy is to restore an age-appropriate diet as soon as possible while preventing GI rest.

Oral rehydration therapy provides a cost-efficient approach to the problem of childhood diarrhea for the patient who is able to drink, is not in shock, and has a relative or other responsible person who can understand the instructions for using the ORS. Such a therapeutic approach avoids the hospitalization of the child and the consequent disruption in the lives of the family members. This treatment approach eliminates the potential complications of intravenous therapy. (See also Chapter 138, Diarrhea and Steatorrhea; and Chapter 353, Dehydration.)

### WHEN TO REFER

- Abnormal electrolytes refractory to fluid therapy
- Seizure or encephalopathy
- Inability to rehydrate by chosen means (oral or intravenous)

### WHEN TO ADMIT

- Failure to rehydrate completely in 6 hours
- Persistent abnormal mental status
- Inability of parent to maintain hydration at home

## Chapter 59

# BLOOD PRODUCTS AND THEIR USES

Vikramjit Kanwar, MRCP(UK), MBA; Michael U. Callaghan, MD; Madhvi Rajpurkar, MD

## INTRODUCTION

This chapter reviews the situations in which pediatricians may encounter blood transfusions, and the current standard practice for transfusing different blood components in children. It addresses how products are processed, which product should be administered, when transfusion should take place, and what complications may result.

In 1901 Karl Landsteiner, “the father of blood transfusion,” discovered the major human blood groups A, B, and O and established that blood transfusion needed to occur between persons with the same blood group to avoid destruction of red blood cells (RBCs). This allowed the first successful blood transfusion to occur, and it was later clarified that a fourth blood group, AB, can accept donations from all the other major blood groups (universal recipient), and that type O blood can be transfused into any of the other 3 major blood groups (universal donor) (see Table 59-1). The primary goal of blood transfusion is to normalize oxygen delivery to the tissues. The ability to separate blood into its components and store them appropriately was a subsequent advance that allowed transfusion of only the required blood component, eg, packed red blood cells (PRBCs) for anemia. Transfusion-acquired viral illnesses, specifically human immunodeficiency virus (HIV) and viral hepatitis, became the next challenge in the 1980s, but better donor screening techniques have made such transfusion-transmitted infections extremely rare.

Although transfusion therapy was originally used primarily to treat inadequate oxygen-carrying capacity related to anemia or blood loss, the ability to store separate blood cell components played a second key role in replacing insufficient coagulation proteins or platelets to provide adequate hemostasis. Less common complications of blood transfusions are now better recognized. This has provided an incentive to pursue a more conservative strategy so that blood components are only administered in situations in which the benefit clearly outweighs risk. The transfusion thresholds set by the American Association of Blood Banks (AABB) rely largely on “expert opinion,” and may not be appropriate for all patients and settings. In general, the physician’s goal is not to restore the circulating amount of a blood component to a normal value, but rather to the lowest level that allows normal functioning for the child’s condition. In deciding whether component replacement is necessary for a particular deficit, pediatricians should always ask 2 key questions: (1) is it essential to correct the deficit immediately through transfusion, and (2) does another method exist to correct the deficit?

**Table 59-1** Major Blood Types and Blood Transfusion

BLOOD TYPE	ANTIGENS ON RBC	CAN DONATE BLOOD TO	ANTIBODIES IN SERUM	CAN RECEIVE BLOOD FROM
O	—	O, A, B, AB	Anti-A and Anti-B	O
A	A	A, AB	Anti-B	A, O
B	B	B, AB	Anti-A	B, O
AB	A and B	AB	—	AB, A, B, O

**Table 59-2** Red Blood Cell (RBC) Products

PRODUCT	HEMATOCRIT	VOLUME/UNIT (mL)	INDICATIONS
Packed RBCs	55%	230–330	Anemia, most commonly used product
Whole blood	40%	570	Acute bleeding, exchange transfusion
Washed RBCs	75%	180	Repeated febrile and allergic reactions despite premedication
Frozen RBCs	75%	180	Rare antigens, IgA deficiency, autologous blood donations

## BLOOD BANKING AND PRODUCTS

The current blood transfusion system in the United States is heavily dependent on carefully screened volunteer blood donors. Donor blood is tested for ABO and Rh blood type, as well as for any unexpected RBC antibodies that may cause problems in a recipient. Screening tests are also performed for evidence of donor infection with hepatitis B and C viruses, HIV-1 and HIV-2, human T-lymphotropic virus (HTLV) 1 and HTLV-2, syphilis, Chagas disease, and West Nile virus. As a result, now the overall risk for HIV and hepatitis C in blood obtained within the United States is less than 1 per 1 million units of PRBCs. It is not uncommon for family members or friends to request directed donations to avoid receiving blood from unknown donors who may be perceived as potentially unsafe. However, this practice not only delays transfusion by 2 to 4 days for testing and processing of donor blood, but actually carries a higher risk of transmissible diseases. It can also increase the risk of HLA sensitization that may adversely affect outcomes in a child preparing for bone marrow transplantation.

Each unit of whole blood is separated into several components after collection, which are then stored in a blood bank. These may be cellular (ie, RBCs, platelets, and rarely, granulocytes) and acellular (fresh frozen plasma [FFP], cryoprecipitate). The storage and administration of each of these components will be addressed herein. In addition, other blood products manufactured by commercial companies include albumin, immune globulin, specific immune globulins, and clotting factor concentrates.

Within the United States, hospital blood banks are registered with the US Food and Drug Administration (FDA) and are regulated (21 CFR 607). Physicians should discuss transfusion needs with their local blood bank; most blood bank staff are happy to assist with questions and queries that may be beyond the scope of this chapter.

### Red Blood Cells

Packed red blood cells are administered in various situations and constitute two-thirds of the units dispensed at blood banks. Various RBC products are available (see Table 59-2), including washed RBCs, which contain less than 1% of original plasma and less than 10% of white blood cells (WBCs), and frozen RBCs, which contain less than 0.025% of original plasma and 1% to 5% of original WBCs. Both preparations are rarely used. In addition, most blood banks no longer store whole blood, and if this is indicated, it is usually derived from saline-reconstituted PRBCs or albumin.

As the most commonly transfused products, PRBCs are transfused primarily to treat inadequate oxygen-carrying capacity related to anemia or blood loss, but also in various other situations and for special populations, discussed later in this chapter. Except for emergency situations, type and crossmatch for ABO and Rh groups are mandatory, and for patients with sickle cell disease, extended phenotyping (looking at other blood groups, eg Cc, Ee, or Kell) is recommended by Rosse and colleagues.

For anemia, PRBCs may be infused as a volume of 10 to 15 mL/kg in infants and 5 mL/kg in older children, and this will normally increase the hemoglobin by 2 to 3 g/dL (20–30 g/L; hematocrit increases by 6%–9%). With very severe chronic anemia (hemoglobin <5 g/dL [50 g/L]) in a patient who is clinically stable (eg, severe iron-deficiency anemia), PRBCs should be given in small aliquots of 5 mL/kg over 4 hours, and repeated until the desired hematocrit is reached.

### Platelets

Platelet concentrates are prepared from whole blood (“random donor platelets”) or collected by apheresis from donors (“single donor platelets”) and can be stored at room temperature (20°C–24°C) with continuous agitation for 5 days. The relatively short shelf life means there is often a shortage of platelets at certain

**Table 59-3**      **Non-Red Blood Cell Products**

PRODUCT	CELL COUNT OR CONTENT	VOLUME/UNIT (mL)	INDICATIONS
Single-donor platelets	$3 \times 10^{11}$ platelets/unit	200–400	Preferred platelet product
Random donor platelets	$5$ to $7 \times 10^{10}$ platelets/unit	40–50	Alternative product if single donor unavailable
Fresh frozen plasma	1 unit	200–220	Multiple factor deficiency; disseminated intravascular coagulation; liver disease or unknown coagulation defect
Cryoprecipitate	>150 mg fibrinogen/unit	15 (5–10 units pooled)	Fibrinogen deficiency, also rich in factors VIII and XIII,

times of the year. ABO- and Rh-compatible platelets should be used when possible. Although HLA-antigens are present on platelets, HLA-typing is not routinely needed.

Platelet transfusions are primarily used in patients who are unable to produce adequate platelets or in those with disseminated intravascular coagulation (DIC). The platelet level that warrants transfusion is controversial, as will be discussed in this chapter. Platelets should not be administered in other situations with thrombocytopenia caused by peripheral destruction (eg, immune thrombocytopenia, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome).

Platelets are administered as 10 mL/kg of single-donor platelets infused over 1 hour, capped at 1 unit. An equivalent volume of random donor platelets (1 unit per 10 kg) may be infused if single-donor platelets are not available. Indications for platelets and other non-RBC products are shown in Table 59-3.

### Granulocytes

White blood cells are difficult to transfuse because they must be collected from ABO-compatible donors via apheresis and administered fresh, and have significant febrile reactions and pulmonary complications. As a result, they are rarely used and colony-stimulating factors such as granulocyte colony-stimulating factor have largely taken their place. The resolving infection in people with neutropenia with granulocytes (RING) clinical trial was unable to demonstrate benefit from granulocyte transfusions in patients with neutropenia and severe infection.

### Plasma

Plasma includes FFP, which can be stored for a year at  $-18^{\circ}\text{C}$ , as well as thawed plasma, which can be stored for 5 days at  $4^{\circ}\text{C}$  and is instantly available. Infused plasma needs to be ABO-compatible with the recipient's RBCs but the Rh type can be ignored. FFP is rich in clotting factors and is often used to correct coagulation defects in DIC, liver disease, unknown coagulation deficiency, and massive transfusions. In addition, FFP may be infused in nonbleeding patients to provide intravascular volume, to correct a prolonged prothrombin time, or to decrease the risk of bleeding with a

planned invasive procedure. None of these practices, however, is supported by any evidence.

Fresh frozen plasma is second only to PRBCs as the most infused blood product. A consensus conference supported by the AABB found that the primary indication should be treatment of a bleeding patient who has a coagulopathy for which a specific clotting factor concentrate was not available. In addition, 2 other situations in which FFP was indicated were (1) massive transfusion, and (2) patients with warfarin-associated intracranial hemorrhage.

The volume of FFP administered at a time is usually 10 to 15 mL/kg.

### Cryoprecipitate

One unit of cryoprecipitate is derived from the controlled thawing of 1 unit of frozen plasma and is rich in fibrinogen (>150 mg per bag). It has a limited number of other coagulation factors such as factor VIII, von Willebrand factor (vWf), and factor XIII for which commercial concentrates are available. It is therefore primarily used for fibrinogen replacement in consumption coagulopathy (eg, massive transfusion, liver failure, or DIC), or rare patients with congenital hypofibrinogenemia.

The blood bank often issues cryoprecipitate as pooled units so it is important to check the dose when ordering.

### Commercial Plasma Products

Plasma products used to treat coagulation disorders are discussed further in Chapter 230, Coagulation Disorders. Recombinant, genetically engineered, non-plasma-derived factor concentrates are replacing blood-derived factors. Factors VIII, IX, activated VIIa, and XIII are currently available in the United States. Several effective methods for inactivating viruses have made such concentrates much safer in recent years. Recombinant activated human factor VII is approved for the treatment or prevention of bleeding in patients with factor VIII or IX deficiency with inhibitors, congenital factor VII deficiency, acquired hemophilia, and Glanzmann thrombasthenia. Prothrombin complex concentrates (4-factor concentrates) are Baglin and colleague's preferred treatment for bleeding in children receiving vitamin K antagonist anticoagulation or correction of a prolonged PT secondary to warfarin

anticoagulation. Antithrombin III concentrate and protein C concentrate are available to treat children with a congenital deficiency in either of those antithrombotic factors.

Albumin is available as a 5% or 25% solution, the latter for children who have hypoproteinemia and need large amounts of albumin without the added sodium load. Albumin is fractionated from pooled plasma and is pasteurized to inactivate viruses.

Immune globulin preparations are also pooled from large numbers of donors. Intravenous immune globulin is used to treat hypogammaglobulinemia, immune thrombocytopenia, Kawasaki disease, and various immune disorders, including neonatal alloimmune thrombocytopenic purpura. Common complications of intravenous immune globulin are allergic reactions and aseptic meningitis; rarely, renal failure may occur. Other immune globulin preparations are available for intramuscular administration and subcutaneous infusion. Intramuscular anti-Rh globulin is given to nonsensitized Rh-negative women during pregnancy, and after delivery, abortion, amniocentesis, or chorionic villus biopsy to prevent sensitization. Intravenous anti-D immune globulin is sometimes used to treat immune thrombocytopenia in Rh-positive patients, but may result in severe hemolytic anemia and renal failure.

## ORDERING TRANSFUSIONS

When ordering blood products for a child, it is important to understand what recipient sample is needed by the blood bank:

- **Type and screen:** *Accurate identification is critical.* Clerical errors when drawing and labeling blood specimens to be sent to the blood bank (or anywhere along the supply chain) are a major cause of severe hemolytic reaction. Usually 1 to 3 mL of blood in a lavender top (EDTA) tube is adequate. ABO and Rh testing, as well as a screen for antibodies is performed. The results are valid for 3 days for patients getting repeat transfusions (see entry on newborns)
- **Type and crossmatch:** In addition to the aforementioned process, the recipient's serum specimen is actually mixed with cells of a donor unit to confirm compatibility, and that donor unit is then reserved for transfusion. Hence, it is important *not* to order crossmatching for cases with a low probability that the blood product will be needed (eg, elective surgery).
- **Extended phenotyping:** Because of the high frequency with which patients with sickle cell disease develop antibodies after transfusion, it is important to look at less common antigens, such as Cc, Ee, Kidd, Kell, and others, when crossmatching blood. Most smaller blood banks will not do this routinely, so it needs to be specified.
- **Newborn type and screen:** Although ABO antigens on RBCs are fully developed at birth, ABO antibodies in the serum are not produced until 3 to 6 months of age, so the presence of any antibodies represents maternal antibodies. Therefore, when type and screen are evaluated in infants younger than 4 months, it is helpful to know maternal blood type, and to have a maternal blood sample. The initial evaluation is valid for the duration of the hospital admission up to 3 months.

Blood products must be stored and handled properly. Once blood has been issued from the blood bank, it should be used promptly within 4 hours and not stored. If administration is delayed, then the blood should be returned to the blood bank immediately. Blood should not have contact with solutions containing dextrose or calcium, and drugs should never be added to a blood component. RBC products (mainly PRBCs) make up approximately two-thirds of transfused units, with the remainder being FFP and platelets, and a small fraction being cryoprecipitate.

## Preparation of Blood Products

Irradiation of blood products to 25 Gy is recommended for blood products being transfused into immune-suppressed children, including (1) children being treated for a malignancy, (2) bone marrow or organ transplant recipients, (3) preterm infants weighing less than 1,200 g and severely ill neonates, (4) fetuses receiving intrauterine transfusions, and (5) children who have severe congenital immunodeficiency disorders. These children are susceptible to transfusion-associated graft vs host disease secondary to lymphocytes in the transfused blood.

Cytomegalovirus (CMV) infection is a risk to neonates, immune-suppressed children (as listed before), and potential stem cell transplant recipients. These children should receive CMV-negative RBCs and platelets. Because CMV is only present in monocytes, acellular products such as FFP and cryoprecipitate do not require testing. Most blood donors are CMV positive, so if CMV-seronegative blood is not available, then leukocyte-reduced blood may be used.

Leukocyte depletion at source with current third-generation blood filters are able to achieve a 3-log reduction (99.9%) of WBCs in cellular components. It is routine practice for all immune-suppressed children (as listed before), and in Canada, several transfusion services in the United States, and many European countries, it is universally performed. Universal leukoreduction may benefit all patients, especially those receiving chronic transfusion, by decreasing the frequency of febrile reactions, alloimmunization, and transmission of CMV infection.

## INDICATIONS FOR RED CELL TRANSFUSION

### Intensive Care

Adequate hemoglobin level to provide tissue oxygenation is the key goal of RBC transfusion in critical care. Large, prospective, randomized trials in adults and children demonstrated that restrictive transfusion (RBC transfusion given at a lower hemoglobin level) was safe and in some cases resulted in superior clinical outcomes compared with liberal transfusion (RBC transfusion given at a higher hemoglobin level). The available evidence strongly suggests that RBC transfusion in pediatric critical care patients is only needed when hemoglobin drops below 7.0 g/dL (70 g/L). Sick and preterm newborns are at risk for neurologic damage, and therefore, the thresholds for transfusion are higher, as discussed later in this chapter.

### Surgery

Children without sickle cell disease undergoing elective surgery require transfusion with PRBCs for a hemoglobin below 8.0 g/dL (80 g/L; hematocrit <24%) with signs and symptoms of anemia in the perioperative period, or blood loss of more than 15% of the blood volume. The extent of surgery, the likelihood of massive blood loss, and coexisting factors such as impaired pulmonary function or inadequate cardiac output must be considered when deciding about the threshold for transfusion. Children with sickle cell disease undergoing elective surgery should receive preoperative transfusions of up to a hemoglobin of 10 g/dL (100 g/L; hematocrit of 30%) to minimize anesthesia risks, but not higher, to avoid the risk of hyperviscosity and stroke.

Autologous blood donations are increasingly used for elective surgery in adolescents, children, and even in infants (although collection is difficult in children weighing <25 kg). The largest experience has been in orthopedic procedures associated with significant blood loss, in cardiac surgery, and in prospective bone marrow donors. Phlebotomies are performed over several weeks before surgery, and the blood is frozen and stored. Salvaging blood intraoperatively and postoperatively, collecting it with special equipment, and reinfusing it are additional techniques to reduce the use of banked donor blood. The use of erythropoietin and iron supplementation for several weeks before surgery is an important adjunct.

### Acute Blood Loss or Trauma

Acute blood loss of up to 10% to 15% of the blood volume can usually be managed by volume replacement with crystalloid fluids, but loss of more than 15% usually requires transfusion of PRBCs. Massive bleeding involving the loss of more than 1 blood volume (7%–9% of ideal body weight) in 24 hours gives rise to shock, secondary consumption coagulopathy, and high mortality. Massive transfusion protocols have been developed to administer non-crossmatched group O Rh PRBCs, FFP with each unit of PRBCs, and platelet transfusions and cryoprecipitate with every other unit; the role of pediatric massive transfusion protocols remains under investigation.

### Sickle Cell Disease

Children with chronic anemia of sickle cell disease often tolerate hemoglobin levels of less than 7 g/dL (70 g/L), and simple PRBC transfusion is only indicated for symptomatic children with aplastic crisis or unilateral acute chest syndrome. PRBC should be leukoreduced and from HbS-negative donors, irradiation is not indicated. Transfusion is not indicated to ameliorate a vaso-occlusive pain crisis. Children with bilateral acute chest syndrome or incipient stroke warrant exchange transfusion or erythrocytapheresis (see the later discussion of Apheresis and Exchange Transfusion). Some patients with sickle cell disease may be on a chronic transfusion program.

### Chronic Transfusion

Children who are transfusion dependent (eg, thalassemia) or have sickle cell disease and have had a

stroke, wherein chronic transfusions are needed to maintain the circulating HbS level at less than 30% have a unique problem. Each unit of PRBC contains approximately 300 mg of elemental iron (daily requirement in childhood is 1–2 mg per day) and chronic transfusion rapidly causes iron overload. Serum ferritin monitoring is mandatory and chelation therapy is required when the ferritin level is less than 1,000 ng/mL; in addition, magnetic resonance imaging may be used to estimate cardiac and liver iron overload.

### Newborns and Infants Younger Than 4 Months

The threshold for transfusion varies significantly, often driven by concern over clinical condition and long term neuro-cognitive outcomes. Every neonatal intensive care unit has minor variations on transfusion threshold, and although multiple suggested guidelines have been created (see Box 59-1), compliance is often poor.

Several questions remain unanswered in newborn transfusion medicine, including the role of transfusions in triggering necrotizing enterocolitis, whether transfusing blood less than 14 days old is potentially beneficial, and the threshold at which transfusion should be performed (liberal vs restrictive policies yielded contradictory long-term results, as shown in Table 59-4).

#### BOX 59-1 Suggested Guidelines for Transfusion of Red Blood Cells in Infants Younger Than 4 Months<sup>a</sup>

1. Hct <20% with low reticulocyte count and signs of anemia (eg, tachycardia, tachypnea, poor feeding)
2. Hct <30% in an infant:
  - a. On <35% O<sub>2</sub> by hood
  - b. On O<sub>2</sub> by nasal cannula
  - c. On continuous positive airway pressure (CPAP) or intermittent mandatory ventilation (or both) with mean airway pressure <6 cm H<sub>2</sub>O
  - d. With significant apnea or bradycardia
  - e. With significant tachycardia or tachypnea
  - f. With low weight gain
3. Hct <35% in an infant:
  - a. On >35% O<sub>2</sub> by hood
  - b. On CPAP or intermittent mandatory ventilation with mean airway pressure >6–8 cm H<sub>2</sub>O
4. Hct <45% in an infant:
  - a. On extracorporeal membrane oxygenation
  - b. With congenital cyanotic heart disease

<sup>a</sup>Guidelines may vary in different institutions.

## INDICATIONS FOR PLATELET TRANSFUSIONS

The essential indication for platelet transfusions is to treat or prevent bleeding. It is worth emphasizing that platelet transfusions are not indicated in immune thrombocytopenia, regardless of the platelet count, except in the setting of intracranial bleeding. Platelet transfusions can actually worsen thrombotic thrombocytopenic purpura or hemolytic uremic syndrome and are contraindicated. Prophylactic platelet transfusions have been administered for patients who are not producing platelets because of chemotherapy or stem cell transplantation at a threshold of 10,000/mL for several years. After initial promising data from a no-prophylaxis strategy, the “platelet dose” (PLADO) trial failed to provide data to support lowering that threshold in children.

The International Collaboration for Transfusion Medicine Guidelines continued with the recommendation that prophylactic platelet transfusion should be performed at a threshold of less than  $10 \times 10^3/\text{mL}$  ( $10 \times 10^9/\text{L}$ ) to decrease the risk of hemorrhage. A low dose of platelets ( $1.41 \times 10^{11}/\text{m}^2$ ) was as effective as higher doses, and although single-donor apheresis platelets are preferred, whole blood-derived platelet concentrates can be used. ABO-compatible platelets improve platelet increments and decrease refractoriness, and for Rh-negative girls or women of child-bearing potential who receive Rh-positive platelets, Rh immunoglobulin to destroy any contaminant RBCs is advisable. Rarely, patients develop HLA antibodies toward platelets, and the degree of benefit from HLA-selected platelets for such patients is uncertain.

Coexistent coagulation disorder, trauma, or surgical bleeding may require patients to receive transfusions of higher platelet counts ( $>50,000/\text{mL}$  [ $>50 \times 10^9/\text{L}$ ]). Preferred thresholds in neonates are higher (see Table 59-5).

## COMPLICATIONS OF TRANSFUSION

Transfusion medicine remains remarkably safe with many of the serious risks of the same magnitude as being struck by lightning. (See Figure 59-1.)

### Acute Hemolytic Transfusion Reaction

Severe, immediate hemolytic transfusion reactions are almost always related to ABO incompatibility and clerical errors, such as incorrect labeling of a blood

**Table 59-5** Platelet Transfusion Guidelines for Newborns

PLATELET COUNT ( $\times 10^3/\text{MCL}$ [ $\times 10^9/\text{L}$ ])	GUIDELINES
<30 (30)	Transfuse all
30–49 (30–49)	Transfuse if: <ul style="list-style-type: none"> <li>• Birth weight &lt;1,500 g and <math>\leq 7</math> d old</li> <li>• Clinically unstable</li> <li>• Concurrent coagulopathy</li> <li>• Previous significant hemorrhage (ie, grade 3 or 4 IVH)</li> <li>• Prior to surgical procedure</li> <li>• Postoperative period (72 h)</li> </ul>
50–100 (50–100)	Transfuse if: <ul style="list-style-type: none"> <li>• Active bleeding</li> <li>• NAIT with intracranial bleed</li> <li>• Before or after neurosurgical procedures</li> </ul>

NAIT, neonatal alloimmune thrombocytopenia.

specimen tube sent to the laboratory for crossmatching or administering a unit of blood crossmatched to a different patient. Acute onset of fever and chills may be accompanied by nausea, abdominal and lower back pain, dyspnea, and hypotension. Renal failure, DIC, jaundice, and shock may rapidly ensue. If such a reaction is suspected, then the transfusion must be stopped and normal saline administered. A blood specimen from the child together with the remainder of the unit of donor blood or the empty bag and any attached blood tubing should be sent to the blood bank immediately. A rapid screening test can be performed by centrifuging a child's blood specimen, which will show pink, red, or brown plasma; a urine sample will show hemoglobin. If a hemolytic reaction occurs, then adequate venous access should be established and the child transferred to an intensive care unit for close monitoring, aggressive fluid administration, and supportive care. Treatment of DIC and renal dialysis may be needed.

**Figure 59-1** Adverse effects of red blood cell transfusion contrasted with other risks. (From Carson JL, Grossman BJ, Kleinman S, et al. *Clinical Transfusion Medicine Committee of the AABB. Red blood cell transfusion: a clinical practice guideline from the AABB.* Ann Intern Med. 2012;157:49–58. Copyright © 2012, The American College of Physicians. Used with permission.)

### Febrile Transfusion Reaction

Fever is the most common transfusion reaction, usually seen in children who receive multiple transfusions, including platelet transfusions, and secondary to contaminating leukocytes. The onset usually occurs 30 minutes to 2 hours after the transfusion is begun, and the child may also have chills. If the reaction is mild, then stopping the transfusion is unnecessary, but it should be slowed. In more severe reactions, temporary interruption of the transfusion is indicated, with an evaluation for a hemolytic reaction, especially if chills and back or abdominal pain are present. Treatment with acetaminophen and, for more severe reactions, corticosteroids, is helpful; for future transfusions, pretreatment with acetaminophen and diphenhydramine may prevent such reactions. Although it has been common practice in many centers to give prophylactic acetaminophen or diphenhydramine before blood transfusion to prevent febrile and allergic reactions, data to support the routine use of premedication are limited; the use of leukoreduced blood products significantly reduces the incidence and severity of reactions.

### Allergic Reactions

The cause of urticarial reactions is unclear, but is associated with antigens in donor plasma, and cannot be prevented by leukodepletion. About 25% of individuals who have congenital immunoglobulin A (IgA) deficiency have antibodies directed against IgA, and these

patients may develop severe anaphylactic reactions to any blood product containing plasma proteins. Anti-IgA antibodies may also develop in normal individuals and result in urticarial or anaphylactic reactions. Treatment with diphenhydramine, and for more severe reactions, corticosteroids is helpful. People who have repeated minor allergic reactions should be pretreated with an antihistamine; corticosteroids may be used if more severe reactions have occurred. Frozen washed RBCs are rarely needed.

### Delayed Hemolytic Transfusion Reaction

Delayed reactions develop on average 10 days after transfusion (range 3–21 days) in children who have been sensitized to red cell antigens with titers too low to be detected before the recent transfusion. This is most commonly seen in children on a chronic transfusion program. An anamnestic reaction may increase antibody production so that hemolysis ensues and the child becomes anemic, often accompanied by fever, jaundice, and hemoglobinuria. Usually, no specific therapy is required, but an additional transfusion may be needed and steroids have sometimes been advocated for treatment.

### Transfusion-Transmitted Infections

Routine screening of donors for antibodies to HIV has been in effect in the United States since 1985, when 27 per 100,000 donations were found to be HIV positive. With current screening tests for donors, the risk

has been reduced to approximately 1 in 2 million. The risk of hepatitis B virus transmission through blood transfusion is essentially at the same incidence as that in the general (nontransfused) population (< 1:200,000–500,000), whereas that for HIV or hepatitis C virus is approximately 1:1,000,000 to 1:2,000,000. Immune-suppressed children, as discussed previously, are at risk for CMV infection; because 60% to 80% of adult donors in the United States are CMV positive, it might not always be easy to find the right blood product.

Other viruses that may be transmitted by transfusion include hepatitis G (not known to cause disease), hepatitis A, and parvovirus. New-variant Creutzfeldt-Jakob disease and other prion-induced diseases affected 129 cases in the United Kingdom, but no cases in the United States have been associated with blood transfusion. As a result, donors who have spent varying periods in the United Kingdom or Europe are deferred.

Because of the significant decrease in transmission of viral disease and increased use of platelet transfusions, bacterial contamination is now a common transfusion-transmitted infection. It is estimated to occur in approximately 1 in 2,000 units of transfused platelets because platelets are stored at room temperature. The American Association of Blood Banks currently requires testing of platelet units for bacterial contamination with an FDA-approved system to reduce the risk to recipients; the BacT/ALERT system is the most commonly used system.

### Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a rare but serious complication of transfusion, occurring most often after transfusion of FFP, but also after other blood products. It has been estimated to occur in 6 in 100,000 transfusions with a 5% mortality, and is the leading cause of transfusion-related death. Patients develop acute respiratory distress caused by noncardiogenic pulmonary edema during or up to 4 hours after transfusion and may require mechanical ventilation. It is caused by anti-HLA or anti-neutrophil antibodies in the donor's plasma, with resultant sequestration of neutrophils in the lung. The treatment is supportive. Mitigation of TRALI has been through preferred use of male donors for plasma and “look back” and removal of donors from the registry who are associated with TRALI.

### Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload has an incidence of 1%, but the careful physician should be able to anticipate volume overload in “at-risk” children and minimize the risk by altering the transfusion rate, volume, or the concomitant use of diuretics.

### Transfusion-Related Immunomodulation

Transfusion of stored RBCs has been shown to increase the risk of nosocomial infections and sepsis in children in intensive care units. The cause for this transfusion-related immunomodulatory effect is unknown but may be related to contaminating leukocytes and their cytokines in RBC units or to release of free iron from RBC breakdown from older transfused units. As a result, leukodepletion and use of

fresher units of PRBCs have been tried with varying results.

## APHERESIS AND EXCHANGE TRANSFUSION

One unit of whole blood is equivalent to approximately twice the blood volume of a full-term neonate (ie, a double volume exchange) and will replace approximately 85% of the infant's RBCs. PRBCs can be reconstituted with FFP, and the blood used should be fewer than 3 to 5 days old. Although manual exchange transfusion can also be performed in older children for various indications, this process can be difficult and time consuming.

Using automated cell separators, whole blood is centrifuged and plasma, platelets, leukocytes, and red cells are separated; the desired component is removed, and the remainder is administered back to the patient. Volume can be replaced with saline, albumin, or FFP. With the exception of erythrocytapheresis, the red cells are returned to the patient. Leukocytapheresis may be performed for patients who have leukemia and very high WBC counts to reduce viscosity and leukostasis until chemotherapy takes effect.

Erythrocytapheresis may be performed for symptomatic polycythemia in children who have cyanotic heart disease by using volume replacement with saline or albumin. In sickle cell disease, red cells may be removed and replaced with those containing hemoglobin A. An exchange of one red cell volume (70 mL/kg  $\times$  patient hematocrit) will reduce the Hb S level to approximately 35%. The RBCs should be reconstituted with albumin or FFP, and an additional RBC infusion can reduce the Hb S level further. The final hematocrit should not be more than 30% to 35%.

Plasma exchange can be performed for thrombotic thrombocytopenic purpura by using FFP for replacement. Autoimmune disorders and related conditions have also been treated with plasmapheresis using albumin for replacement, but several of those indications have been discredited.

## Chapter 60

# ANTIMICROBIAL THERAPY

Blaise Congeni, MD; Cecilia Di Pentima, MD, MPH

The use of antimicrobial agents to treat diseases caused by bacteria is part of the day-to-day practice of pediatrics. Antimicrobial therapy continuously evolves; even experts in infectious diseases have trouble staying abreast of new agents and their pharmacologic properties and pharmacodynamics. The physician should know how to use a limited number of antimicrobial agents well rather than have a meager knowledge of many.

## APPROACH TO ANTIMICROBIAL THERAPY

There are 3 important questions that should be answered before antimicrobial therapy is initiated: Where is the infection (anatomic site)? What pathogens usually cause infections at this site? And which antimicrobial agents, given by what route of administration, will achieve effective concentrations at this site? The answers to the 2 initial questions are usually addressed critically by the physician. However, selection of an antimicrobial agent is more likely to be based on a *bug-drug* relationship than on knowledge about a drug's ability to achieve an effective concentration at the site of infection.

The anatomic site of most bacterial infections can be identified by a combination of historical information and findings on physical examination. When the site of infection is more obscure, diagnostic studies such as radiographs, radionucleotide scans, computed tomography scans, magnetic resonance imaging, and ultrasound evaluation are often helpful.

The pediatrician can usually develop a list of potential bacterial pathogens based on the site of infection and the patient's age, habitat, history of exposures,

and clinical signs and symptoms. The site of infection and possible causative agents help the physician decide what (if any) specimens should be cultured for bacteria and whether the laboratory should be alerted to use special culture media or techniques. Selecting an antimicrobial agent based on its ability to achieve effective concentrations at the site of infection requires a working concept of effective concentration. To define an effective concentration, the physician must first review some of the basic pharmacodynamics of antimicrobial agents.

## PHARMACODYNAMICS AND PHARMACOKINETICS

Pharmacodynamics describes the relationship between the serum concentration of the drug and its pharmacologic and toxicologic effects. Pharmacokinetics, on the other hand, describes the absorption, distribution, and elimination of drugs. Physicians are most often interested in the relationship between drug concentration and the antimicrobial effect, the interrelationship between pharmacokinetics and pharmacodynamics. Once administered, an antimicrobial agent is initially distributed throughout the intravascular volume and the extracellular fluid of tissues with high perfusion rates. The drug enters tissues that are not highly perfused at a slower rate. Some antimicrobial agents, such as the  $\beta$ -lactams, are distributed only in extracellular fluid, whereas others distribute intracellularly as well (rifampin, trimethoprim-sulfamethoxazole [TMP-SMX]).

## Correlation of Drug Concentration and Clinical Effect

Antibiotics can be divided into 2 different groups based on their pattern of bactericidal activity. The first group of agents exhibits a greater rate and extent of bactericidal activity the higher the drug concentration. These agents exhibit concentration-dependent killing. Aminoglycosides, fluoroquinolones, metronidazole, and perhaps macrolides exhibit this type of bactericidal activity. In contrast, other antibiotics demonstrate bactericidal activity that is independent of drug concentration as long as the concentration exceeds the minimal inhibitory concentration (MIC) for a certain portion of the dosing interval. These agents demonstrate minimal concentration-dependent killing, but instead, their bactericidal activity depends on the time of exposure. Time-dependent agents include the  $\beta$ -lactam antibiotics, vancomycin, and clindamycin.

## Postantibiotic Effect

For some antibiotics, continued suppression of bacterial growth occurs even after concentrations of the agent have declined below levels that are sufficient to inhibit growth. This circumstance is termed *postantibiotic effect* (PAE). All antimicrobial agents exhibit PAEs in vitro against susceptible gram-positive bacteria. Prolonged PAEs for gram-negative bacteria are observed only after exposure to antibiotics that inhibit protein synthesis or nucleic acid synthesis. A notable

exception is the carbapenems, which produce prolonged PAEs with strains of *Pseudomonas aeruginosa*.

### Relationship of Pharmacokinetic and Pharmacodynamic Parameters and Efficacy

When a time-dependent agent is used, organisms begin to regrow after the serum concentration of the antimicrobial agent has fallen below the MIC. Consequently, the most effective treatment regimens will allow for drug concentrations at the site of infection to be above the MIC for as large a part of the dosing interval as possible. For example, a cure of 85% to 100% can be anticipated when the drug concentration exceeds the MIC for at least 40% of the dosing interval for time-dependent agents such as  $\beta$ -lactams.

Infrequent dosing of concentration-dependent agents such as aminoglycosides and fluoroquinolones is effective. During the 1990s, several studies reported clinical efficacy that was at least equal when the entire aminoglycoside dose was given as a single daily dose compared with divided doses. This approach allows for a single peak concentration at least 10-fold higher than the MIC. Although considerable debate continues, toxicity does not seem to be increased and actually seems more favorable; some investigators have suggested that toxicity depends on the length of time the drug is present in drug-sensitive tissues (eg, the kidney, the inner ear) rather than on the highest concentration attained in the serum at any point.

### Minimal Inhibitory and Minimal Bactericidal Concentrations

An antimicrobial agent's activity against specific bacteria in vitro is expressed as the agent's MIC or minimal bactericidal concentration (MBC). To determine the MIC, bacteria are grown in broth to a concentration of 100,000 ( $10^5$ ) microorganisms per milliliter. The broth containing the bacteria, which is clear to the naked eye, is then placed in a series of test tubes, and a decreasing amount of antimicrobial agent is added to each test tube. The broth containing the bacteria and antimicrobial agent is incubated overnight and then examined for visible turbidity (turbidity represents bacterial growth). The test tube with the smallest concentration of antimicrobial agent that remains clear to the naked eye represents the MIC. To determine whether the antibiotic is bactericidal, the tubes that remained clear are quantitatively subcultured onto agar plates. After overnight incubation, bacterial colonies are counted. Each colony represents 1 bacterium that survived, or 1 colony-forming unit (CFU). The smallest amount of antibiotic that results in the death of 99,900 (99.9%) of the original 100,000 microorganisms per milliliter inoculum (a 1,000-fold reduction) is the MBC. MIC and MBC results are reported in micrograms of antimicrobial agent per milliliter of broth required to inhibit or kill the microorganism, respectively.

### Serum Inhibitory and Bactericidal Titers

Antimicrobial activity in vivo can be approximated by determining the inhibitory or bactericidal titers. Although the test is usually performed using serum, it

can be done with most body fluids that are clear, except urine. The test is performed by growing organisms to  $10^5$  CFU/mL of broth, as in determining the MIC. However, instead of adding known concentrations of antimicrobial agent to each test tube, serial 2-fold dilutions of serum (or other body fluids) are added to sequential tubes (undiluted serum is added to the first tube, serum diluted 1:2 to the second tube, 1:4 to the third, and so on). After incubation overnight, the tubes are examined for visible turbidity; the most dilute sample that has no visible turbidity is the serum inhibitory titer. To determine whether the bacteria are being killed, the broth is cultured quantitatively as for the MBC, and the most dilute specimen that results in the death of 99.9% of the original inoculum is the serum bactericidal titer. Formerly, serum bactericidal levels were used to monitor adequacy of therapy when patients being treated for osteomyelitis or sometimes endocarditis were switched from parenteral to oral therapy. Unfortunately, few laboratories are able to offer this test any longer.

### Tolerance

Tolerance to an antibiotic occurs when organisms are inhibited by the typical concentration of a bactericidal agent but require a higher concentration of the agent to achieve a bactericidal effect. The clinical significance of tolerance is still controversial, but this phenomenon may apparently be important with infections that require bactericidal activity to effect a cure.

### Bacteriostatic versus Bactericidal Agents

Most infections in children do not require a bactericidal antimicrobial agent. In general, bactericidal agents are needed for optimal treatment of bacterial endocarditis, meningitis, and osteomyelitis. The effectiveness of bacteriostatic agents depends on the host's ability to opsonize and phagocytize bacteria that have been inhibited; thus, bactericidal agents are usually necessary to treat bacterial infections in a neutropenic host.

### Role of the Laboratory in Antimicrobial Therapy

Laboratory testing is usually unnecessary for choosing antimicrobial agents for most bacterial infections treated in the ambulatory setting. For example, otitis media is the most common infection of children that is treated with antimicrobial agents in the ambulatory setting. The site of infection is identified by physical examination. The bacterial pathogens that cause otitis media have been well established, and several antimicrobial agents have been shown to produce a clinical and microbiologic cure when given orally. Only if empirical therapy fails might performing a tympanocentesis become necessary to obtain a specimen for isolating the bacteria and performing antibiotic susceptibility tests. The physician can manage common infections such as impetigo, cellulitis, cervical adenitis, local abscesses, and conjunctivitis without obtaining specimens for culture simply by knowing the usual pathogens and their susceptibility to antimicrobial agents.

### Culture and Susceptibility

When therapy fails, when the patient is seriously ill or immunocompromised, or when the clinical situation is unusual, the first step in choosing antimicrobial therapy is to obtain appropriate specimens for culture. When bacterial pathogens are isolated from a normally sterile specimen, antimicrobial susceptibility is tested. Susceptibility is tested either by determining the MIC as described previously or by using the disk diffusion method.

In the disk diffusion method of susceptibility testing, a culture plate is inoculated with the bacteria to be tested, and paper disks containing standardized concentrations of antimicrobial agents are placed on the surface of the culture medium. The culture plates are incubated, and the moisture from the medium allows the antimicrobial agents to diffuse out of the paper disks. The farther from the disk the diffusion reaches, the lower will be the concentration of antimicrobial agent. If the bacteria are inhibited by the antibiotic, then a zone around the disk forms in which the bacteria do not grow. The zone of inhibition is measured after overnight incubation, and based on its diameter, the organism is determined to be *susceptible* or *resistant* to the antimicrobial agent. The interpretation of a result indicating *intermediate* or *indeterminate* is currently undergoing change. Intermediate likely means susceptible but dose dependent. An organism reported to be susceptible by disk means that 95% of the strains of these bacteria are inhibited by serum concentrations of the antimicrobial agent if the antimicrobial agent is given at the usual dose by the usual route of administration for an infection with that organism. This concentration is called the MIC<sub>95</sub>. Clearly, the site of infection, the proposed antibiotic's activity against the pathogen, and the concentration of the antibiotic that can be achieved at the site of infection must all be considered. Pediatric dosages for antibacterial drugs are given in Table 60-1 and Table 60-2.

*Susceptible to ampicillin* has very different meanings, depending on the organism being tested. Gram-negative organisms or enterococci being reported as susceptible to ampicillin (see Table 60-1 and Table 60-2) means that 95% of these organisms are inhibited by serum concentrations of 8 mcg/mL or less of ampicillin. For gram-positive cocci, susceptible means that 95% are inhibited by serum concentrations of 0.2 mcg/mL or less or 40 times less ampicillin than is required to inhibit gram-negative enterics. For *Haemophilus influenzae*, susceptible means that serum concentrations of 2 mcg/mL or less are required to inhibit 95% of all strains. Unless the MIC has been determined for the individual isolate, the physician must assume that MIC<sub>95</sub> must be achieved at the site of infection to inhibit the isolate.

There are 2 modifications of the disk diffusion method that provide additional information when selecting an antibiotic for certain infections. The *e test* uses a strip instead of a disk. An antibiotic gradient is applied, and the zone of inhibition enables the laboratory to determine an approximated MIC by observing where growth occurs on the gradient. This test is most often used to determine MICs for different antimicrobials for *Streptococcus pneumoniae*.

The *D test* is used to determine whether inducible resistance for clindamycin is likely for the offending staphylococcal isolate. The clindamycin disk is placed adjacent to the erythromycin disk. The zone of inhibition between the clindamycin and erythromycin disks is blunted, hence the appearance of a zone that resembles a *D*. Despite the presence of a large zone of inhibition, the staphylococcal isolate is considered resistant to clindamycin (Figure 60-1).

### PROPERTIES OF CLASSES OF ANTIBACTERIAL AGENTS

Because of the large number of antimicrobial agents currently available, usually several are equally effective for a given infection. The antimicrobial agents preferred by a physician reflect the drugs' cost and availability, physician's training, and local practices. In general, knowing how to use a small number of antimicrobial agents well is far better than knowing all of the possible alternatives. The most frequently prescribed antimicrobial agents and their selected pharmacologic and pharmacodynamic information are listed in Table 60-1 and Table 60-2. These tables are an example of the information a physician should have at hand when using antimicrobial agents.

#### Penicillins

##### Mechanism of Action

Although the general mechanism of action of penicillins is to inhibit cell wall synthesis, precisely how they do this is unknown. Current evidence, however, points to inhibition of transpeptidation. Most bacteria have penicillin-binding proteins (PBPs) in their cell membranes. Several PBPs can be found, and the number and type vary from organism to organism. The activity of penicillins generally correlates with the number of high-affinity PBPs the organism has.

#### Bacterial Resistance

Bacterial resistance to penicillins can be based on 3 principal mechanisms: enzymatic degradation, reduced penetration of the agent to the target site, and alteration in the PBP. Inactivation of the penicillin as a result of degradation caused by a penicillinase produced by the bacteria has been the most common mechanism of resistance for this class of agents.  $\beta$ -Lactamase enzymes hydrolyze the  $\beta$ -lactam ring. A variety of  $\beta$ -lactamases have been identified and are classified based on substrate preference. Both gram-positive and gram-negative organisms can produce  $\beta$ -lactamases, and production of these enzymes is mediated by either plasmid or chromosomal mechanisms.

Occasionally, resistance is mediated by failure of the penicillin to reach the site of infection. Some bacteria are resistant because, as a result of shape or electric charge, penicillin cannot reach the binding site. Although this mechanism is clinically less significant, given structural considerations it is more likely encountered with gram-negative organisms such as *Enterobacter*.

**Table 60-1** Antibacterial Drugs for Neonates ( $\leq 28$  Postnatal Days of Age)<sup>a</sup>

DOSE PER KG AND FREQUENCY OF ADMINISTRATION					
DRUG	ROUTE	BODY WEIGHT ≤2 KG		BODY WEIGHT >2 KG	
		≤7 DAYS OF AGE	8–28 DAYS OF AGE <sup>b</sup>	≤7 DAYS OF AGE	8–28 DAYS OF AGE
AMINOGLYCOSIDES <sup>c,d</sup>					
Amikacin	IV, IM	15 mg every 48 h	15 mg every 24h	15 mg every 24 h	17.5 mg every 24 h
Gentamicin	IV, IM	5 mg every 48 h	5 mg every 36 h	4 mg every 24 h	4-5 mg every 24 h
Tobramycin	IV, IM	5 mg every 48 h	5 mg every 36 h	4 mg every 24 h	4-5 mg every 24 h
CARBAPENEMS					
Imipenem/cilastatin <sup>e</sup>	IV	20 mg every 12 h	25 mg every 12 h	25 mg every 12 h	25 mg every 8 h
Meropenem <sup>f</sup>	IV	20 mg every 12 h (≤14 days of age)	20 mg every 8 h (>14 days of age)	20 mg every 8 h (>14 days of age)	30 mg every 8 h (≤14 days of age)
CEPHALOSPORINS <sup>f</sup>					
Cefepime <sup>g</sup>	IV, IM	30 mg every 12 h	30 mg every 12 h	30 mg every 12 h	30 mg every 12 h
Cefotaxime	IV, IM	50 mg every 12 h	50 mg every 8–12 h	50 mg every 12 h	50 mg every 8 h
Cefazolin	IV, IM	25 mg every 12 h	25 mg every 12 h	25 mg every 12 h	25 mg every 8 h
Ceftazidime	IV, IM	50 mg every 12 h	50 mg every 8–12 h	50 mg every 12 h	50 mg every 8 h
Cefoxitin	IV, IM	35 mg every 12 h	35 mg every 8 h	35 mg every 8 h	30 mg every 6 h
Ceftriaxone <sup>h</sup>	IV, IM	50 mg every 24 h	50 mg every 24 h	50 mg every 24 h	50 mg every 24 h
Cefuroxime	IV, IM	50 mg every 12 h	50 mg every 8–12 h	50 mg every 12 h	50 mg every 8 h
PENICILLINS					
Ampicillin <sup>f</sup>	IV, IM	50 mg every 12 h <sup>i,j</sup>	50 mg every 8 h <sup>i</sup>	50 mg every 8 h <sup>i,j</sup>	50 mg every 6 h <sup>i</sup>
Nafcillin, oxacillin <sup>f</sup>	IV, IM	25 mg every 12 h	25 mg every 8 h	25 mg every 8 h	25 mg every 6 h
Penicillin G crystalline <sup>f</sup>	IV, IM	25,000–50,000 U every 12 h	25,000–50,000 U every 8 h	25,000–50,000 U every 12 h	25,000–50,000 U every 8 h

Antibacterial Drugs for Neonates ( $\leq 28$  Postnatal Days of Age)<sup>a</sup>—cont'd

DOSE PER KG AND FREQUENCY OF ADMINISTRATION					
DRUG	ROUTE	BODY WEIGHT $\leq 2$ KG		BODY WEIGHT $> 2$ KG	
		$\leq 7$ DAYS OF AGE	8–28 DAYS OF AGE <sup>b</sup>	$\leq 7$ DAYS OF AGE	8–28 DAYS OF AGE
Metronidazole <sup>k</sup> [15 mg/kg loading dose all categories (for body weight $\leq 2$ kg or $> 2$ kg, and for $\leq 7$ days of age or 8–28 days of age)]	IV	7.5 mg every 12 h	7.5 mg every 12 h	7.5 mg every 8 h	7.5 mg every 6 h
Vancomycin	IV	See comment <sup>l</sup>			

IM, intramuscular; IV, intravenous; PO, oral.

We gratefully acknowledge the review and comments on this table by John Van den Anker, MD, PhD.

<sup>a</sup>From American Academy of Pediatrics. Antibacterial drugs. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015: 882–883

<sup>b</sup>May use the longer dosing interval in extremely low birth weight ( $< 1,000$  g) neonates until 2 weeks of life.

<sup>c</sup>Dosages for aminoglycosides may differ from those recommended by the manufacturer and approved by the US Food and Drug Administration.

<sup>d</sup>Optimal, individualized dosage should be based on determination of serum concentrations.

<sup>e</sup>Accumulation of cilastatin may occur in neonates with multiple doses.

<sup>f</sup>Higher doses than those listed may be required for meningitis.

<sup>g</sup>50 mg/kg/dose may be required for *Pseudomonas* infections.

<sup>h</sup>Neonates should not receive ceftriaxone intravenously if they also are receiving, or are expected to receive, intravenous calcium in any form, including parenteral nutrition. See Bradley JS, Wessel RT, Lee L, Nambiar S. Intravenous ceftriaxone and calcium in the neonate: assessing the risk for cardiopulmonary adverse events. *Pediatrics*. 2009;123(4):e609–e613.

<sup>i</sup>Some experts recommend 75 mg/kg/dose every 6 h for group B streptococcal meningitis for all weight groups.

<sup>j</sup>100 mg/kg/dose every 12 hours also is acceptable for treatment of presumed early-onset group B streptococcal septicemia without meningitis.

<sup>k</sup>Metronidazole kinetics are best described by postmenstrual (postconceptional) age, which is equivalent to gestational age plus chronologic age. For postmenstrual age  $< 34$  weeks, 7.5 mg/kg every 12 h; for 34–40 weeks, 7.5 mg/kg every 8 h; for  $> 40$  weeks, 7.5 mg/kg every 6 h. All categories should receive a 15-mg/kg loading dose.

<sup>l</sup>Dosing algorithm for vancomycin is based on serum creatinine concentration (which will take approximately 5 days after birth to reasonably reflect neonatal renal function); if  $< 0.7$  mg/dL, then 15 mg/kg every 12 h; if 0.7–0.9 mg/dL, then 20 mg/kg every 24 h; if 1–1.2 mg/dL, then 15 mg/kg every 24 h; if 1.3–1.6 mg/dL, then 10 mg/kg every 24 h; if  $> 1.6$  mg/dL, then 15 mg/kg every 48 h.

During the past decade, alteration in PBPs has become an important mechanism of resistance. This mechanism of resistance is responsible for methicillin resistance seen with *Staphylococcus aureus*. Alteration of PBP also is responsible for the reduced susceptibility of *S pneumoniae* to  $\beta$ -lactams seen in drug-resistant *S pneumoniae* (DRSP). Use of  $\beta$ -lactamase T-stable agents under these circumstances is not effective.

Infections in children caused by DRSP seem to be decreasing as a result of widespread use of the conjugate pneumococcal vaccine. However, community-associated infections with methicillin-resistant *S aureus* (MRSA) have increased dramatically. Infections caused by MRSA may require treatment with antimicrobics that do not inhibit cell wall synthesis by binding to PBPs. Agents frequently used for such infections include vancomycin, linezolid, TMP-SMX, and clindamycin. Tetracyclines and fluoroquinolones may also be used when the age of the patient permits. When selecting a specific antistaphylococcal agent, the physician should be guided by the severity of the infection, as well as by local susceptibility patterns. For example, in life-threatening infections, vancomycin is usually used as a first-line therapy.

### Classification

Based on their specific antibacterial activity, penicillins can be classified loosely as natural, penicillinase resistant, amino, antipseudomonal, and extended spectrum. The physician should be well versed in the use of 1 penicillin from each class.

### Pharmacologic Properties

Penicillins vary greatly in absorption after oral administration, with penicillin V, amoxicillin, cloxacillin, and dicloxacillin having the greatest absorption. Food reduces the absorption of oxacillin and dicloxacillin but not of penicillin V or amoxicillin. Procaine penicillin G and benzathine penicillin G are absorbed slowly after intramuscular injection and are given every 12 to 24 hours and every 15 to 20 days, respectively. Penicillins are excreted by renal tubular cells and have a very short half-life, ranging from less than 30 minutes to slightly more than 1 hour. Penicillins are distributed to most areas of the body if inflammation is present. However, they are poorly lipid soluble and do not enter the central nervous system (CNS) well, even if inflammation is present. Penicillins do not enter cells well. Passage of penicillins from the serum of a

DRUG GENERIC (TRADE NAME)	GENERIC AVAILABLE	ROUTE	DOSAGE PER KG PER DAY		COMMENTS
			MILD TO MODERATE INFECTIONS	SEVERE INFECTIONS	
AMINOGLYCOSIDES <sup>b</sup>					Individualize dose and frequency based on analysis of serum concentrations. <sup>b</sup>
Amikacin	Y	IV, IM	Inappropriate	15–22.5 mg in 2–3 doses, or 15–20 mg in 1 dose	Aminoglycosides may be given once daily, or in divided doses. Measured serum concentrations should guide ongoing therapy. Higher doses are appropriate for patients with cystic fibrosis.
Gentamicin	Y	IV, IM	Inappropriate	6–7.5 mg in 3 doses, or 5–7.5 mg in 1 dose	Aminoglycosides may be given once daily, or in divided doses. Measured serum concentrations should guide ongoing therapy.
Neomycin	Y	PO	100 mg in 4 doses	100 mg in 4 doses	For some enteric infections.
Tobramycin	Y	IV, IM	Inappropriate	6–7.5 mg in 3–4 doses, or 5–7.5 mg in 1 dose	Aminoglycosides may be given once daily, or in divided doses. Measured serum concentrations should guide ongoing therapy. Higher doses are appropriate for patients with cystic fibrosis.
CARBAPENEMS <sup>c</sup>					
Doripenem (Doribax)	N	IV	Inappropriate	60 mg in 3 doses (daily adult dose, 1,500 mg in 3 doses)	Not yet FDA approved for children, but under study. Not studied in meningitis. The generation of each agent is listed as a rough guide to antimicrobial spectrum.
CEPHALOSPORINS <sup>c</sup>					
Imipenem/cilastatin (Primaxin)	Y	IV	Inappropriate	60–100 mg in 4 doses (daily adult dose, 1–4 g)	Caution in use for treatment of CNS infections because of increased risk of seizures. Higher doses for more severe infections or <i>Pseudomonas aeruginosa</i> infections.
Meropenem (Merrem)	Y	IV	Inappropriate	30–60 mg in 3 doses (daily adult dose, 1.5–6 g)	Higher dose (120 mg in 3 doses) used for treatment of meningitis.
Ertapenem (Invanz)	N	IV/IM	Inappropriate	30 mg in 2 doses (adult dose, 1 g, once daily)	Poor activity against <i>Pseudomonas</i> and <i>Acinetobacter</i> species.
Cefaclor (Ceclor)	Y	PO	20–40 mg in 2 or 3 doses (daily adult dose, 750 mg–1.5 g)	Inappropriate	Second-generation.

**Table 60-2** Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period<sup>a</sup>—cont'd

DRUG GENERIC (TRADE NAME)	GENERIC AVAILABLE	ROUTE	DOSAGE PER KG PER DAY		COMMENTS
			MILD TO MODERATE INFECTIONS	SEVERE INFECTIONS	
Cefadroxil (Duricef)	Y	PO	30 mg in 2 doses (daily adult dose, 1–2 g)	Inappropriate	First-generation.
Cefazolin	Y	IV, IM	25–50 mg in 3 doses (daily adult dose, 3 g)	100–150 mg in 3 doses (daily adult dose, 4–6 g)	First-generation. Limited data on dosages above 100 mg/kg/day.
Cefdinir (Omnicef)	Y	PO	14 mg in 1 or 2 doses (max, 600 mg/day)	Inappropriate	Extended-spectrum third generation. Inadequate activity against penicillin- resistant pneumococci.
Cefditoren (Spectracef)	Y	PO	≥12 y: 400–800 mg total daily dose (not per kg) in 2 doses	Inappropriate	Extended-spectrum third general. Contraindicated in patients with carnitine deficiency.
Cefepime (Maxipime)	Y	IV, IM	100 mg in 2 doses (daily adult dose, 2–4 g)	100–150 mg in 2–3 doses (daily adult dose, 4–6 g)	Extended-spectrum fourth generation. Higher dose (150 mg in 3 doses) used for <i>Pseudo-</i> <i>monas</i> infections, or for febrile neutropenia.
Cefixime (Suprax)	N	PO	8 mg in 1 or 2 doses (daily adult dose, 400 mg)	Inappropriate	Extended-spectrum third generation. Inadequate activity against penicillin- resistant pneumococci.
Cefotaxime (Claforan)	Y	IV, IM	50–180 mg in 3 or 4 doses (daily adult dose, 3–6 g)	200–225 mg in 4 or 6 doses (daily adult dose, 8–12 g)	Extended-spectrum third generation. Up to 300 mg in 4 or 6 doses for meningitis.
Cefotetan	Y	IV, IM	60 mg in 2 doses (daily adult dose, 2–4 g)	100 mg in 2 doses (daily adult dose, 4–6 g)	Second-generation. A cephamycin, with en- hanced anaerobic activity. Not FDA approved for use in children.
Cefoxitin (Mefoxin)	Y	IV, IM	80 mg in 3–4 doses (daily adult dose, 3–4 g)	160 mg in 4 doses (daily adult dose, 6–12 g)	Second-generation. A cephamycin, with enhanced anaerobic activity. Active against <i>Bacteroides</i> <i>fragilis</i> .
Cefpodoxime (Vantin)	Y	PO	10 mg in 2 doses (daily adult dose, 200–400 mg, 800 mg for SSTIs)	Inappropriate	Extended-spectrum third generation.
Cefprozil (Cefzil)	Y	PO	15–30 mg in 2 doses (daily adult dose, 0.5–1 g)	Inappropriate	Second-generation.
Ceftaroline (Teflaro)	N	IV	Inappropriate	Adults, 1,200 mg per day in 2–3 doses	Extended-spectrum fifth generation with activity against CA MRSA. Not yet FDA approved for children, but under study.

DRUG GENERIC (TRADE NAME)	GENERIC AVAILABLE	ROUTE	DOSAGE PER KG PER DAY		COMMENTS
			MILD TO MODERATE INFECTIONS	SEVERE INFECTIONS	
<b>STREPTOGRAMIN</b> Quinupristin/ dalfopristin (Synercid)	N	IV	Inappropriate	For children ≥12 y of age: 15 mg in 2 doses (daily adult dose, same)	Moderate activity against <i>Staphylococcus aureus</i> . Limited experience in children.
<b>SULFONAMIDES</b> Sulfadiazine	Y	PO	120–150 mg in 4–6 doses (daily adult dose, 4–6 g)	120–150 mg in 4–6 doses (daily adult dose, 4–6 g)	
Trimethoprim (TMP)-sulfa- methoxazole (SMX) in 1:5 ratio (Bactrim, Septra)	Y	PO, IV	6–12 mg of TMP component in 2 doses (daily adult dose, 320 mg TMP)	same	2 mg of TMP component once daily for UTI prophylaxis. See p 641 for <i>Pneumocystis jirovecii</i> dosing.
<b>TETRACYCLINES</b> Tetracycline (Sumycin)	Y	PO	25–50 mg in 4 doses (daily adult dose, 1–2 g)	25–50 mg in 4 doses (daily adult dose, 1–2 g)	Responsible for staining of developing teeth; routine use only in children 8 y or older. Exceptions for circumstances in which the benefits of therapy exceed the risks and al- ternative drugs are less effective or more toxic found on p 873.
Doxycycline (Vibramycin)	Y	PO, IV	2–4 mg in 1–2 doses (daily adult dose, 50–200 mg)	4 mg/kg per day, divided every 12 hours, intrave- nously or orally (maximum 100 mg/dose)	Adverse effects similar to those of other tetracy- cline products except that risk of dental stain- ing in children younger than 8 y with doxycy- cline is unlikely at the dose and duration recommended to treat serious infections.
Minocycline (Dynacin, Minocin)	Y	PO, IV	4 mg in 2 doses (daily adult dose, 200 mg)	4 mg in 2 doses (daily adult dose, 200 mg)	Responsible for staining of developing teeth; routine use only in children 8 y or older.
<b>VANCOMYCIN</b> (Vancocin)	Y	IV	40–45 mg in 3–4 doses (daily adult dose, 1–2 g)	45–60 mg in 3–4 doses (daily adult dose, 2–4 g)	Measured serum concen- trations should guide ongoing therapy.

AOM, acute otitis media; CA MRSA, community-associated methicillin-resistant *Staphylococcus aureus*; CNS, central nervous system; FDA, US Food and Drug Administration; IM, intramuscular; IV, intravenous; PO, oral; SSTI, skin and soft tissue infection; UTI, urinary tract infection.

<sup>a</sup>From American Academy of Pediatrics. Antibacterial drugs. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015: 885–895.

<sup>b</sup>Once-daily aminoglycoside dosing may provide equal efficacy with reduced toxicity and may be used as an alternative to multiple daily dosing. See Contopoulos-Iannidis DG, Giotis ND, Baliatsa DV, Iannidis JP. Extended-interval aminoglycoside administration for children: a meta-analysis. *Pediatrics*. 2004;114(1):e111–e118, and Best EJ, Gazarian M, Cohn R, Wilkinson M, Palasanthiran P. Once-daily gentamicin in infants and children: a prospective cohort study evaluating safety and the role of therapeutic drug monitoring in minimizing toxicity. *Pediatr Infect Dis J*. 2011;30(10):827–832.

<sup>c</sup>Children with a history of an IgE-mediated, immediate hypersensitivity reaction to penicillins (urticaria, angioedema, bronchospasm, anaphylaxis) who require treatment with an alternate β-lactam should be considered for skin testing (if available) to confirm the allergy, and/or undergo supervised graded clinical challenge or desensitization with the alternate β-lactam agent under the supervision of an expert in drug allergy and desensitization.

<sup>d</sup>Ciprofloxacin is FDA approved for use in patients younger than 18 years for complicated UTI and postexposure inhalation anthrax but also has been studied in other infections. Levofloxacin is FDA approved for postexposure inhalation anthrax and plague, but has been studied in children and adolescents for treatment of AOM, community acquired pneumonia.

<sup>e</sup>Available in 2-mL prefilled syringes. Each 1 mL contains 300,000 units benzathine plus 300,000 units procaine (600,000 total units per mL).

**Figure 60-1** Positive D test. Petri plate with zone of inhibition surrounding disks.

pregnant woman to her fetus depends on the degree of protein binding present; little of highly protein-bound penicillin reaches the fetus.

### Side Effects

The most important adverse reactions to penicillins are caused by hypersensitivity; they range from skin rashes to anaphylaxis. Anaphylactic reactions to penicillin are immunoglobulin E (IgE) mediated and occur in approximately 1 of every 500 courses of treatment (0.2%); approximately 1 of every 100,000 courses results in a fatality (0.001%). The morbilliform rashes seen during therapy with penicillins probably are IgM mediated and often disappear even when therapy is continued. Less common reactions include serum sickness, exfoliative dermatitis, and Stevens-Johnson syndrome.

Patients who experience significant type 1 reactions such as anaphylaxis following use of a penicillin generally should not be treated with a cephalosporin or other  $\beta$ -lactam. Cross-reactivity, however, is probably less of a problem than previously thought. Patients with non-type 1 reactions can generally be treated with a cephalosporin, for example. Cross-reactivity is not to the shared  $\beta$ -lactam ring but to shared side chains. Using an agent with dissimilar side chains probably poses little risk. Patients who experience idiopathic reactions, such as a morbilliform rash, when treated with a penicillin can be treated with a cephalosporin. It is therefore critical to document the exact nature of the reaction following any antibiotic, including penicillins and cephalosporins.

### Penicillin Desensitization

At times, administering penicillin to a penicillin-sensitive patient may be necessary, for example, in a patient with meningococcal meningitis who is allergic to cephalosporins and penicillins. When penicillin is administered to a patient who may have an anaphylactic reaction, immunotolerance to penicillin can be

achieved by starting with very small doses. An effective protocol is to administer 5 U of penicillin G intracutaneously in the forearm, and then, at 60- to 90-minute intervals increase the dose to 10, 100, 1,000, 10,000, and 50,000 U. If the intradermal doses are tolerated, intravenous penicillin can be instituted.

### Use of Selected Penicillins

The natural penicillins listed in Table 60-1 and Table 60-2 are penicillin G (aqueous, procaine, and benzathine) and penicillin V. These antimicrobial agents are most active against both aerobic and anaerobic gram-positive cocci, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, *Fusobacterium* species, *Eikenella* species, *Listeria monocytogenes*, and *Borrelia burgdorferi*. Penicillins are still the mainstay of treatment for infections caused by group A  $\beta$ -hemolytic streptococci, group B streptococci, *S pneumoniae*, *N meningitidis*, and *L monocytogenes*. Penicillin is also the drug of choice for acute infections with *B burgdorferi* (Lyme disease) in children and for infections caused by anaerobes normally found in the mouth.

The potassium salt of penicillin G is usually used and is almost exclusively given intravenously. Either procaine or benzathine preparations are used for intramuscular administration. When given intramuscularly, aqueous penicillin G is excreted very rapidly; when given by mouth, it is poorly absorbed, and very low serum concentrations are achieved with these preparations; they can be used only for exquisitely sensitive organisms and generally should not be used to treat CNS infections. Procaine penicillin can be used in a newborn to treat neurosyphilis. Penicillin V is well absorbed from the gastrointestinal tract and is therefore preferred for oral administration. Peak serum concentrations and MIC<sub>95</sub> equivalents for susceptibility by disk are listed for individual penicillins in Table 60-1 and Table 60-2.

Ampicillin has the same general activity as penicillin, but it also is active against *Escherichia coli*, *Proteus mirabilis*, *Salmonella* species, and *Shigella* species and is more active against group D streptococci and *L monocytogenes*. Amoxicillin differs from ampicillin in molecular composition only by the presence of a hydroxyl group. Because amoxicillin is absorbed much better than ampicillin, peak serum concentrations of amoxicillin after oral administration are equal to those achieved with an equivalent dose of ampicillin given intramuscularly. The antimicrobial activity of amoxicillin is virtually identical to that of ampicillin, except that it is not useful in the treatment of shigellosis; because of the increased absorption of amoxicillin, less drug is available in the intestinal tract.

Several fixed-combination  $\beta$ -lactam- $\beta$ -lactamase inhibitors are available.  $\beta$ -Lactamase inhibitors include clavulanic acid, sulbactam, and tazobactam. There are 4 agents currently available: amoxicillin-clavulanate (Augmentin), ampicillin-sulbactam (Unasyn), ticarcillin-clavulanate (Timentin), and piperacillin-tazobactam (Zosyn). Piperacillin-tazobactam does not have a pediatric indication for its use. The  $\beta$ -lactamase inhibitor extends the activity of the  $\beta$ -lactam to include some organisms that produce  $\beta$ -lactamase. Amoxicillin-clavulanate, for example, is active against  $\beta$ -lactamase-producing *S aureus*, *H influenzae*, *N gonorrhoeae*, and

*Moraxella catarrhalis* that otherwise would be resistant to amoxicillin. The MIC for *E coli*, *Klebsiella* species, *Proteus* species, and *Bacteroides fragilis* ranges from 8 to 16 mcg/mL. This combination is no more active than amoxicillin for *S pneumoniae* strains that are resistant to penicillin. Ampicillin in a fixed combination with sulbactam is marketed as Unasyn for intravenous use only. The activity of ampicillin-sulbactam is similar to that of ampicillin-clavulanate, and this agent is frequently used in adults and children for respiratory infections and infections in which anaerobes are likely to be pathogens, such as intraabdominal or intraoral infections. Safety and efficacy for intraabdominal infections in children have not been established. Ticarcillin-clavulanate and piperacillin-tazobactam use a  $\beta$ -lactam that is an extended-spectrum penicillin with antipseudomonal activity, thereby extending the spectrum of these fixed combinations further. These agents would be more appropriate for infections in which gram-negative organisms, including *Pseudomonas*, are thought to be pathogens.

Nafcillin is one of several penicillinase-resistant penicillins used primarily to treat infections caused by *S aureus*, excluding MRSA. Most strains of *S aureus* are inhibited by concentrations of 2 to 3 mcg/mL. Because nafcillin is highly protein bound, methicillin is preferred for newborns when the possibility of kernicterus is a concern because the amount of albumin available for binding bilirubin will be diminished. Absorption of nafcillin from the gastrointestinal (GI) tract is erratic; it should not be given orally. Dicloxacillin is absorbed from the GI tract more consistently and is a good oral agent for treating *S aureus* infections. The oral suspension of dicloxacillin has a very bitter taste, which can create problems with compliance.

Several antipseudomonal and extended-spectrum penicillins are currently available. In general, *Pseudomonas* infections should be treated with a combination of one of these agents plus an aminoglycoside, both for synergy and for reducing the emergence of resistant bacteria. A possible exception to this rule is for the treatment of a urinary tract infection caused by *P aeruginosa*. Mezlocillin has the antipseudomonal activity of carbenicillin and ticarcillin; it is also more active against enterococci, *Klebsiella* species, *H influenzae*, and *B fragilis*. An important point to remember is that a report of *susceptible to mezlocillin* means that concentrations as high as 64 mcg/mL will be needed to inhibit 95% of the strains tested; this circumstance is compensated for by the high serum concentrations achieved when the drug is given intravenously (the peak serum concentration is 300 mcg/mL after an intravenous dose of 4 g).

Treating multidrug-resistant strains has become more of a problem, especially given the fact that few new antibiotics have been developed during the past decade. A way to address this problem, especially for resistant gram-negative rod infections, such as those seen in nosocomial infections, is to take advantage of pharmacokinetic/pharmacodynamic principles while still employing available agents. For example, a recent retrospective cohort study compared piperacillin-tazobactam given by extended infusion (4 hours) to a 30-minute infusion for treating patients infected with *P aeruginosa* in the intensive care setting. Both 14-day

mortality and length of stay were significantly improved in the prolonged infusion group. These investigators took advantage of the time-dependent killing pharmacokinetic profile seen with this extended-spectrum penicillin.

## Cephalosporins

### Mechanism of Action

Similar to penicillins, cephalosporins are  $\beta$ -lactam antibiotics that interfere with cell wall synthesis. However, the precise mechanism is not known, and the effects of cephalosporins on bacteria range from lysing the organism to producing bacteria that have unusual forms.

### Bacterial Resistance

Bacterial resistance to cephalosporins can arise if the cephalosporin is inactivated by  $\beta$ -lactamase, if it is unable to reach antibiotic-binding proteins, if the organism does not have appropriate binding sites, or if tolerance develops (see the previous discussion of penicillins).

### Classification

In the 1970s and 1980s, more new cephalosporins were introduced for general use than any other type of antimicrobial agent. Currently, ceftriaxone and cefotaxime are 2 of the agents most commonly used for the empirical therapy of the febrile infant. The usual classification system for cephalosporins is based on antibacterial activity and is divided into first, second, and third generations. Some experts have recently added a fourth generation. This classification system seems more useful for parenteral agents and may result in very dissimilar agents being grouped together. In general, the first-generation cephalosporins have good activity against gram-positive cocci except enterococci, coagulase-negative staphylococcal species, and MRSA; they have limited activity against gram-negative organisms except *E coli*, *Klebsiella pneumoniae*, and *P mirabilis*. Activity of these agents against Enterobacteriaceae is unpredictable; the physician should be guided by in vitro susceptibility testing. Organisms susceptible to one cephalosporin of this class are generally susceptible to all. The second-generation cephalosporins have the general activity of the first generation but are somewhat more active against gram-negative organisms, including *H influenzae*. Third-generation cephalosporins are more active than second-generation drugs against gram-negative organisms but are less active against some gram-positive organisms, especially *S aureus*, than are the first-generation drugs.

Cefepime is a fourth-generation cephalosporin with activity similar to cefotaxime, but it additionally demonstrates better activity against some gram-negative organisms, such as *P aeruginosa*.

### Pharmacologic Properties

Because of the number of cephalosporins and the wide variations in pharmacology, each drug should be considered individually.

### Side Effects

The side effects seen with cephalosporins are generally the same as those seen with penicillins. Hypersensitivity reactions are the most common side effects.

Although immunologic studies have shown a substantial cross-reactivity between penicillins and cephalosporins, in practice only 5% to 10% of persons who have hypersensitivity reactions to penicillins have them to cephalosporins. In general, if a patient has had only a nonurticarial rash as the manifestation of penicillin hypersensitivity, then using cephalosporins is safe. For patients who have had urticaria or an anaphylactic reaction in response to penicillins, cephalosporins should be used with great caution. Recent studies have suggested that the frequency of cross-sensitivity between penicillins and cephalosporins is substantially less than the figures cited previously. Allergy to cephalosporins in patients truly allergic to penicillins is more common with first-generation cephalosporins and is seen with agents with identical side chains. The fact that both the penicillins and the cephalosporins share an identical  $\beta$ -lactam ring seems much less important relative to predicting cross-sensitivity than previously thought. Less common side effects with cephalosporins are nephrotoxicity, diarrhea, alcohol intolerance, and bleeding.

### Use of Selected Cephalosporins

**FIRST-GENERATION CEPHALOSPORINS.** First-generation cephalosporins are used to treat infections caused by gram-positive cocci when penicillin cannot be used, to treat infections caused by methicillin-sensitive *S aureus*, and to provide coverage against *E coli*, *K pneumoniae*, and *P mirabilis*. Cefazolin is preferable to cephalothin because it has greater activity against *E coli* and *Klebsiella* species, achieves higher peak serum concentrations, and has a longer half-life. The peak serum concentration of cefazolin after a dose of 1 g given intravenously is 188 mcg/mL; the serum half-life is 1½ to 2 hours. Susceptible by disk means that 95% of the bacteria tested are inhibited by 8 mcg/mL or less. The longer half-life compared with antistaphylococcal penicillins, nafcillin, or cephalothin makes cefazolin a particularly attractive agent for patients who are not hospitalized. Cefazolin can be given 3 times per day compared with the other agents, which require dosing 4 times per day. Cephalexin (Keflex) is a first-generation cephalosporin that can be given orally. A peak serum concentration of 16 mcg/mL can be achieved with a dose of 0.5 g. The antibacterial activity of cephalexin is similar to that of cefazolin. Cefadroxil achieves peak serum concentrations and has antimicrobial activity similar to that of cephalexin but is excreted more slowly, allowing administration at 12- to 24-hour intervals.

**SECOND-GENERATION CEPHALOSPORINS.** Based on activity, second-generation cephalosporins should be divided further into 2 separate groups. The true cephalosporins of the second generation include cefuroxime and cefamandole.

Cefuroxime was used widely in children for the treatment of infection when gram-positive cocci such as *S aureus* and *H influenzae* were considered likely pathogens. Many of these infections are now treated with the third-generation cephalosporins, ceftriaxone, or cefotaxime because of improved penetration into the cerebrospinal fluid and because of the possibility of *S pneumoniae* as a pathogen in these circumstances. Cefuroxime is the only second-generation cephalosporin that achieves therapeutic concentrations

in cerebrospinal fluid (CSF). For a time, cefuroxime was advocated as single-drug therapy for bacterial meningitis in infants and children older than 2 months. However, cefuroxime does not sterilize the CSF as rapidly as does ampicillin plus chloramphenicol or selected third-generation cephalosporins, and should not be used to treat meningitis. Cefuroxime can be used when parenteral coverage for both *S aureus* and *H influenzae* is desirable in a patient who has no CNS infection.

The second-generation cephamycins include cefoxitin, cefotetan, and cefmetazole. These agents are rarely used in children because more suitable agents are available. Cefoxitin is highly resistant to  $\beta$ -lactamases and is more active against anaerobes, especially *B fragilis*, than other cephalosporins. It is not as active as other second-generation cephalosporins against *H influenzae* and Enterobacteriaceae, nor is it as active against gram-positive cocci as first-generation cephalosporins. Cefotetan is more active against aerobic gram-negative bacilli than cefoxitin but is less active against aerobic gram-positive cocci. Cefmetazole seems to be more active against *S aureus* than either cefoxitin or cefotetan but is less active than cefotetan against Enterobacteriaceae and less active than cefoxitin against *B fragilis*. Because of its activity against anaerobes plus some gram-positive and gram-negative aerobes, cefoxitin has proved useful in the treatment of pelvic inflammatory disease and lung abscesses. The peak serum concentration after a dose of 1 g given intravenously is approximately 22 mcg/mL, and the serum half-life is approximately 50 minutes. Susceptible by disk means that the MIC<sub>95</sub> for the organism is 8 mcg/mL or less. Use of cefoxitin declined dramatically in the 1990s because of the development of safer, more effective agents. Fixed-combination  $\beta$ -lactam- $\beta$ -lactamase inhibitors, such as Unasyn, are more active against anaerobes and have better activity against gram-positive cocci, including *S aureus*. Metronidazole and carbapenems are also more active against anaerobes than cefoxitin. Consequently, these agents are preferred in clinical situations in which cefoxitin may have been used in the past.

Second-generation cephalosporins available for oral administration include cefaclor (Ceclor), cefuroxime axetil (Ceftin), cefprozil (Cefzil), and loracarbef (Lorabid). Loracarbef is technically a carbacephem rather than a cephalosporin. These agents are used primarily as the second- or third-line agents to treat upper respiratory infections (eg, otitis media, sinusitis) in patients who have not responded to less expensive first-line agents such as amoxicillin. The structure and spectrum of activity of loracarbef are very similar to those of cefaclor.

**THIRD-GENERATION CEPHALOSPORINS.** The third-generation cephalosporins are more active than even the first- or second-generation drugs against gram-negative organisms, but these agents are less active against *S aureus*. Cefotaxime and ceftriaxone are the most active of the cephalosporins against *S pneumoniae* and other streptococci, including many strains that are resistant to penicillin.

Third-generation cephalosporins can be thought of as those that have a role in treating *Pseudomonas*

infections and those that do not. Cefotaxime and ceftriaxone do not have activity against *P aeruginosa*. Cefotaxime, the initial third-generation cephalosporin to be used widely in the United States, is still useful clinically. Ceftriaxone is very similar to cefotaxime in antibacterial activity but has a much longer half-life. Both cefotaxime and ceftriaxone are active against most gram-positive aerobes except enterococci and *L monocytogenes*. Neither is active against MRSA or coagulase-negative staphylococci. Both are active against most gram-negative aerobic bacteria, except for *Pseudomonas* species. The diacetyl breakdown product of cefotaxime also has a broad range of activity, but specific activity is less than that of cefotaxime itself. The peak serum concentration after intravenous administration of 1 g of cefotaxime is approximately 40 mcg/mL, compared with 150 mcg/mL for ceftriaxone. The serum half-life of cefotaxime is approximately 1 hour, compared with 4 to 6 hours for ceftriaxone. Because ceftriaxone is excreted slowly, a peak serum concentration of 50 mcg/mL is achieved in adults after a dose of 0.5 g is given intramuscularly. Susceptible by disk means that the MIC<sub>95</sub> of either drug for the bacteria tested is 8 mcg/mL or less.

The subsequent third-generation cephalosporins that have good antipseudomonal activity are cefoperazone and ceftazidime. Ceftazidime is more active than cefoperazone against *Pseudomonas* in vitro but is less active than cefotaxime against gram-positive organisms. Whether or not ceftazidime should be used as a single agent to treat *Pseudomonas* infections is still controversial. In adults, the peak serum concentration of ceftazidime after 1 g is given intravenously is 85 mcg/mL; the serum half-life is approximately 1 hour, 48 minutes. Approximately 90% of *Pseudomonas* isolates are inhibited by 8 mcg/mL or less of ceftazidime.

There are 4 third-generation cephalosporins currently available for oral use: cefixime (Suprax), cefpodoxime proxetil (Vantin), ceftibuten (Cedax), and cefdinir (Omnicef). Cefixime and ceftibuten have a similar spectrum; consequently, they are grouped together. They have limited activity against some gram-positive cocci such as *S pneumoniae* and no activity against *S aureus*. Both are active against the gram-negative bacilli responsible for most urinary tract infections. Because *S pneumoniae* coverage is incomplete, these agents are recommended only as second-line agents for the treatment of otitis media and only if treatment with an antimicrobial that has good antipneumococcal activity fails when used alone. Both of these agents are active against *Streptococcus pyogenes* and can be used for pharyngitis. The usual dose of cefixime is 8 mg/kg/day given as a single dose; the usual dose of ceftibuten is 9 mg/kg/day given once daily or divided into 2 equal doses.

Cefpodoxime proxetil and cefdinir have a spectrum of activity for gram-negative microorganisms that is similar to those of other oral third-generation cephalosporins. These agents, however, have good activity against gram-positive cocci, including *S pneumoniae*, *S pyogenes*, and *S aureus*, methicillin-sensitive strains. Cefpodoxime achieves higher tissue concentrations in the lungs and tonsils than do other cephalosporins. The usual dosage is 5 mg/kg every 12 hours, with a maximal dose of 400 mg/day for

otitis media and 200 mg/day for pharyngitis or tonsillitis. The dosage of cefdinir for children 6 months to 12 years of age is 14 mg/kg/day in 1 or 2 divided doses. Although the oral third-generation cephalosporins are effective in treating bacterial pneumonia, otitis media, tonsillitis, and pharyngitis, equally effective and less expensive alternatives are available.

**FOURTH-GENERATION CEPHALOSPORINS.** Currently, cefepime (Maxipime) is available for use in individuals older than 2 months. This agent has been tentatively classified as a fourth-generation cephalosporin. Available only for parenteral use, it is unique compared with other cephalosporins because of its broad spectrum of activity against both gram-positive cocci, including methicillin-sensitive *S aureus*, *S pneumoniae*, and *S pyogenes*, as well as most aerobic gram-negative bacilli, including *P aeruginosa*. This agent has a half-life of 2 hours, which permits dosing twice daily at 100 mg/kg/day. It has been used primarily in adults for the treatment of pneumonia and febrile neutropenia. Although it seems to penetrate into the CSF, it does not have an indication for the treatment of meningitis. Cefepime has been evaluated in pediatric patients with bacterial meningitis and has been found to be effective; however, US Food and Drug Administration approval for this indication has not been obtained.

Recently, a new class of cephalosporin, ceftaroline (Teflaro), has been approved for use in patients older than 18 years with skin and skin structure infections as well as community-acquired pneumonia. Trials are currently underway in pediatric patients. This novel cephalosporin has activity against both methicillin-sensitive and methicillin-resistant *S aureus* and *S pneumoniae* as well as common gram-negative pathogens.

### Other $\beta$ -Lactam Antibiotics

There are 4 other  $\beta$ -lactam antibiotics—imipenem, meropenem, ertapenem (carbapenems), and aztreonam (monobactam)—that have a limited role in the treatment of bacterial infections in children. This class of drugs is generally considered treatment of choice for those extended-spectrum  $\beta$ -lactamase-positive pathogens. Imipenem and meropenem have an extremely broad range of activity that covers most gram-positive organisms, including enterococci, *Listeria* species, and methicillin-susceptible staphylococci, which includes coagulase-negative staphylococci. Strains of *S pneumoniae* that demonstrate intermediate or high levels of resistance to penicillin are frequently susceptible to these agents. Imipenem and meropenem also inhibit most Enterobacteriaceae, *P aeruginosa*, and *Pseudomonas maltophilia*, as well as most anaerobic bacteria. Ertapenem has a longer half-life compared with the other available carbapenems, permitting less frequent dosing. It is not as reliably active against gram-negative aerobes when compared with imipenem or meropenem. Carbapenems are generally considered drugs of choice for organisms producing extended spectrum  $\beta$ -lactamase.

Because imipenem is rapidly destroyed by a renal peptidase, it is supplied in a fixed combination with a dehydropeptidase inhibitor called cilastatin. In adults, 500 mg of imipenem with cilastatin given intravenously produces an average peak serum concentration of 33 mcg/mL; the serum half-life is approximately

1 hour. The MIC<sub>95</sub> of bacteria susceptible by disk is 4 mcg/mL or less. Imipenem's broad spectrum of antimicrobial activity is seldom required in clinical practice.

The major risk factor that has somewhat limited the usefulness of the carbapenems is seizure activity. The risk for seizures seems to be somewhat lower with meropenem compared with imipenem. Consequently, carbapenems should be used with caution in patients who have associated risk factors that may increase the likelihood of seizures, such as renal failure and CNS conditions, including meningitis.

Imipenem recently has been licensed for use in patients as young as 1 week. Meropenem is indicated for use in children 3 months or older. Ertapenem does not have an indication for use in children younger than 3 months, and no indication has been found for patients with meningitis. Given the broad spectrum of activity, these agents are occasionally useful in resistant infections with *S pneumoniae*; in patients with mixed infections, including those caused by anaerobes; and in patients with febrile neutropenia.

Aztreonam, a monobactam, has little activity against gram-positive or anaerobic bacteria because these bacteria have little PBP 3, which is the primary binding site for aztreonam. On the other hand, aztreonam is very active against Enterobacteriaceae (MIC,  $\leq 0.5$  mcg/mL) and moderately active against *P aeruginosa* (MIC,  $\leq 16$  mcg/mL). In adults, 1 g of aztreonam given intravenously results in a peak serum concentration of approximately 125 mcg/mL; the serum half-life is 1 hour, 42 minutes. Susceptible by disk means that the MIC<sub>95</sub> will be 8 mcg/mL or less. The use of aztreonam in children is scant.

## Aminoglycosides

### Mechanisms of Action

Aminoglycosides inhibit bacterial protein synthesis by interfering with bacterial ribosomes at the interface between the smaller and larger ribosome subunits. A second mechanism, not yet known, is necessary to fully explain bacterial killing.

### Bacterial Resistance

There are 3 mechanisms of bacterial resistance to aminoglycosides. Ribosomal resistance occurs when alteration in the smaller ribosomal subunit results in its inability to bind streptomycin. The most common mechanism of resistance is the production of bacterial enzymes that inactivate aminoglycosides. Because aminoglycosides are similar in structure, certain enzymes can inactivate more than one aminoglycoside. The capacity to produce aminoglycoside-inactivating enzymes is inherent among gram-negative aerobic bacteria and seldom occurs by induction. The number and types of enzymes vary among places and populations. As an aminoglycoside becomes used more widely, bacteria that produce inactivating enzymes become more prevalent. The ability to produce inactivating enzymes is carried by plasmids and transferred among gram-negative bacteria. Amikacin seems to be an unsuitable substrate for many of these inactivating

enzymes; consequently, amikacin may be active against some organisms resistant to other aminoglycosides, including gentamicin and tobramycin.

The third mechanism of resistance to aminoglycosides is bacterial impermeability to aminoglycosides. Permeability mutants are generally not very virulent. When an organism is susceptible to tobramycin or gentamicin (or both) but is resistant to amikacin, the amikacin resistance must be based on amikacin's inability to enter the organism. This property must be the reason because the only enzyme produced by gram-negative organisms that inhibits amikacin also inhibits tobramycin and gentamicin.

### Pharmacologic Properties

Aminoglycosides are absorbed poorly or not at all after oral administration. Absorption after intramuscular administration is excellent, with the peak serum concentration occurring 30 to 90 minutes after administration. The serum concentration after intravenous administration over 20 to 30 minutes is approximately the same as after intramuscular administration. Aminoglycosides do not cross cell membranes well and therefore achieve poor concentrations inside most cells except renal tubular cells, which actively transport these agents. In general, only low concentrations of aminoglycosides are achieved in the CNS, eyes, biliary tract, or prostatic fluid. Aminoglycosides do enter synovial fluid well.

Because aminoglycosides are excreted by glomerular filtration, care must be taken to adjust the dose for patients who have renal failure. After filtration, some of the aminoglycoside dose is reabsorbed by the proximal renal tubular cells; this reabsorption probably plays a role in nephrotoxicity caused by these drugs. By convention, the drug is infused over a 60-minute period, and the peak serum concentration is measured 30 minutes after the infusion is completed. With intramuscular administration, the peak serum concentration is measured 1 hour later. Because the therapeutic-to-toxic index is very low for aminoglycosides, the serum concentration should be monitored closely.

### Side Effects

The 2 most common side effects of aminoglycosides are ototoxicity and nephrotoxicity. Ototoxicity is generally considered to be reversible and is caused by destruction of the outer hair cells in the organ of Corti and is possibly related to the concentration of aminoglycoside in the endolymph or perilymph that bathes these cells. The relationship between serum concentrations and the development of ototoxicity remains unclear. Some investigators have suggested that elevated trough concentrations predispose a patient to ototoxicity. Others have recently postulated that once-daily dosing of aminoglycosides may actually reduce the likelihood of ototoxicity by reducing drug accumulation in the inner ear.

Hearing loss generally begins at higher frequencies than those commonly used for conversation. Consequently, routine screening of hearing may be useful in patients at risk for auditory ototoxicity such as those who have cystic fibrosis and are receiving repeated

courses of aminoglycosides. Vestibular toxicity is another manifestation of ototoxicity that is thought to be irreversible and can be very disabling. Transient elevations in aminoglycoside concentrations probably do not affect hearing.

Nephrotoxicity is exhibited as a decrease in the glomerular filtration rate. As with ototoxicity, the relationship between serum concentrations and the development of nephrotoxicity is not completely understood. Nephrotoxicity is generally mild and reversible. Associated risk factors frequently are found in patients who have nephrotoxicity, including concurrent medications and illnesses. Some investigators have suggested that the risk for nephrotoxicity is reduced by administering the entire daily aminoglycoside dose once a day. Both ototoxicity and nephrotoxicity seem to occur less often in children than in adults. Nonetheless, monitoring the serum concentration is important to make sure it is both safe and therapeutic, especially when dosed 2 or 3 times daily.

Aminoglycosides can also cause neuromuscular paralysis, particularly when given along with curare-like drugs, in the presence of botulin toxin, and in patients who have myasthenia gravis. Neuromuscular paralysis does not usually occur if aminoglycosides are given intramuscularly. Neuromuscular paralysis can be treated by administering calcium.

### Use

Streptomycin, the first aminoglycoside used clinically, is used almost exclusively to treat tuberculosis, but it is also used to treat tularemia, plague, and brucellosis. Neomycin is used primarily to reduce the number of bacteria in the large bowel. It is given by mouth, and very little reaches the bloodstream.

Three aminoglycosides—gentamicin, tobramycin, and amikacin—are currently used systemically to treat serious infections caused by gram-negative aerobic bacteria. In general, no evidence has been uncovered that one of these aminoglycosides is clinically superior to another in the treatment of susceptible bacteria. Tobramycin is more active against *P. aeruginosa* than gentamicin or amikacin, but differences in its clinical effectiveness have not been observed. Tobramycin and amikacin are somewhat less nephrotoxic than gentamicin. Amikacin is susceptible to inactivation by one aminoglycoside-inactivating enzyme, whereas tobramycin and gentamicin are inactivated by at least 6 enzymes. Thus, organisms are less likely to be resistant to amikacin than to either tobramycin or gentamicin. Because amikacin is less toxic on a weight basis, a larger dose is given and a higher peak serum concentration is achieved. With a dose of 7.5 mg/kg of amikacin given intravenously, the peak serum concentration averages 38 mcg/mL. At a dose of 2 mg/kg of tobramycin or gentamicin, the peak serum concentration ranges from 3 to 12 mcg/mL. All 3 drugs have a serum half-life of 2 to 2½ hours. The MIC<sub>95</sub> of amikacin for bacteria reported susceptible by disk is 16 mcg/mL or less; the MIC<sub>95</sub> of gentamicin or tobramycin is 4 mcg/mL or less.

Once-daily dosing of aminoglycosides has been found to have several advantages over dosing every 8 to 12 hours. The pharmacodynamic model presented

earlier suggests that because aminoglycosides kill in a concentration-dependent manner, once-daily dosing should offer more rapid and effective killing of bacteria. Once-daily dosing results in a higher peak serum concentration, an acceptably low trough concentration, and possibly a lower incidence of nephrotoxicity and ototoxicity. Dosing once daily also facilitates more convenient administration and reduces costs. Gentamicin and tobramycin are dosed at 4 to 7 mg/kg/day, producing a peak serum concentration that ranges from 10 to 20 mcg/mL and a trough concentration below 2 mcg/mL. Actually, the serum concentration will be below the MIC for a substantial portion of the dosing interval. Amikacin is dosed at 15 mg/kg/day, with a resulting peak serum concentration of 54 mcg/mL and a trough concentration below 5 mcg/mL. Monitoring serum concentrations in patients receiving once-daily dosing is generally accomplished by obtaining a single serum sample 6 hours after the dose. A nomogram is available that then enables the physician to decide whether that dose is administered most appropriately once a day, every 36 hours, or once every other day. Despite studies showing an efficacy equivalent to divided daily doses, once-daily administration of aminoglycosides has not become widespread in pediatrics. Most adult patients, however, are treated using a single daily dose. Some investigators have cautioned that once-daily dosing should not be used for patients who have enterococcal endocarditis, are newborns, or are febrile and neutropenic.

## Sulfonamides and Trimethoprim

### Mechanisms of Action

Sulfonamides inhibit bacterial growth by reducing bacterial synthesis of folic acid, resulting in a decrease in bacterial nucleotides. Trimethoprim inhibits bacterial dihydrofolate reductase, which is the step in folic acid synthesis that follows the step inhibited by sulfonamides. The combination of trimethoprim and sulfamethoxazole results in a synergistic, sequential blockage of folic acid.

### Bacterial Resistance

Resistance to sulfonamides can be based on overproduction of substrate by the bacteria or a change in enzyme structure to one that has diminished sulfonamide binding. Trimethoprim resistance also may be caused by a decline in the bacteria's capacity to bind the drug or to a change in dihydrofolate reductase. Resistance to both drugs can result if an organism develops decreased permeability to the drugs. Resistance occurs less often when the combination TMP-SMX is used.

### Pharmacologic Properties

The sulfonamides currently used in the United States, either alone or in combination with trimethoprim, are sulfisoxazole (Gantrisin), sulfamethoxazole, and sulfadiazine. Sulfonamides are usually given orally, but intravenous preparations of sulfadiazine and sulfisoxazole are available. These sulfonamides are quickly and completely absorbed from the stomach and small intestine. Sulfonamides are distributed throughout the body, including the CSF. They readily cross the

placenta and are found in fetal blood. Sulfonamides are partially metabolized in the liver, and free drug metabolites are excreted by glomerular filtration.

Trimethoprim is also usually given orally and is readily absorbed. It is well distributed throughout the body, with the CSF concentration reaching approximately 40% of the serum concentration. Excretion is primarily by renal tubular secretion.

### Side Effects

A wide variety of toxicities are associated with sulfonamides, ranging from GI upset, headache, and rash to serum sickness and hepatic necrosis. Severe hypersensitivity reactions can occur, such as toxic epidermal necrolysis, Stevens-Johnson syndrome, erythema nodosum, vasculitis, and anaphylaxis. Blood cell disorders, including aplastic anemia, granulocytopenia, thrombocytopenia, and leukopenia, have been attributed to sulfonamides. Patients who have glucose-6-phosphate dehydrogenase (G6PD) deficiency are at heightened risk for aplastic anemia. Sulfonamides should not be taken during the last month of pregnancy because they cross the placenta and compete for bilirubin-binding sites, increasing the risk for kernicterus. All of the side effects associated with sulfonamides can occur with trimethoprim as well, the most common being GI upset and hypersensitivity reactions. With prolonged use, trimethoprim can interfere with folate metabolism, resulting in a megaloblastic anemia. This condition can be prevented by administering folic acid.

### Use of Trimethoprim-Sulfamethoxazole and Selected Sulfonamides

The combination of trimethoprim and sulfamethoxazole was introduced initially to treat urinary tract infections. However, because of its wide range of antibacterial activity, it has proved useful in several bacterial infections. Gram-positive organisms susceptible to TMP-SMX include both coagulase-positive and coagulase-negative staphylococci, *S pneumoniae*, enterococci, and *Listeria* species. Currently, more than 95% of MRSA strains that are community associated are susceptible to TMP-SMX. Hospital-associated strains are not as likely to be susceptible. TMP-SMX also is inhibitory for a wide range of gram-negative aerobic organisms, including *E coli*, *Klebsiella* species, *Salmonella* species, *Shigella* species, *H influenzae*, and *N meningitidis*.

Until recently, TMP-SMX was used primarily in the treatment of acute urinary tract infections and for long-term bacterial suppression in patients who have chronic or recurrent urinary tract infections. Currently, however, TMP-SMX is a preferred agent for the treatment of mild-to-moderate infections caused by community-associated MRSA. Respiratory tract infections, otitis media, sinusitis, prostatitis, orchitis, and epididymitis are also treated on occasion with TMP-SMX. It remains the drug of choice for treating *Pneumocystis jiroveci* (formerly *carinii*) infections and has proved effective in preventing *P jiroveci* infection in children who have malignancies. Many adults infected with human immunodeficiency virus (HIV) do not tolerate TMP-SMX well. To date, however, this situation has not been a major problem in HIV-infected

infants. The peak serum concentrations for both drugs, reached approximately 2 hours after an oral dose, average 2 mcg/mL for trimethoprim and 60 mcg/mL for sulfamethoxazole. After repeated doses, the peak serum concentration of trimethoprim approaches 9 mcg/mL. The MIC<sub>95</sub> for bacteria susceptible to the combination is 2 mcg/mL or less for trimethoprim and 38 mcg/mL or less for sulfamethoxazole. However, the combination usually is synergistic in vivo.

Sulfisoxazole is used primarily to treat acute urinary tract infections or to effect long-term suppression in patients who have chronic or recurrent urinary tract infections. Sulfadiazine is effective prophylaxis for close contacts of patients who have *N meningitidis* infections if the strain is known to be susceptible (see Chapter 366, Meningococcemia). The peak serum concentrations after an oral dose of 2 g range from 30 to 60 mcg/mL for sulfadiazine, 40 to 50 mcg/mL for sulfisoxazole, and 80 to 100 mcg/mL for sulfamethoxazole.

Topical sulfonamides are used primarily in 2 settings. Ophthalmic preparations of sulfacetamide are used to treat acute conjunctivitis and as adjunctive therapy in the treatment of trachoma. Silver sulfadiazine is used in the topical treatment of burns. In this combination, sulfadiazine serves principally as a vehicle for the release of silver ions, which have an antibacterial effect.

### Macrolides and Azalides: Erythromycin, Clarithromycin, and Azithromycin

#### Mechanism of Action

Macrolides inhibit RNA-dependent protein synthesis at the step of chain elongation.

#### Bacterial Resistance

Bacteria that lack the appropriate ribosomal binding site are resistant to erythromycin, as are bacteria that are less permeable to the drug. The presence of an efflux pump results in low-level resistance for streptococcal strains. Methylase resistance, conferred by the *erm* gene, is the most common mechanism of resistance seen in the United States.

### Erythromycin

#### Pharmacologic Properties

Several erythromycin preparations are available for oral administration. Erythromycin base is destroyed by gastric acid and is therefore useful only when given as an enteric-coated tablet. Pediatric preparations use the ester or ester salt derivatives of erythromycin because they are acid stable, soluble, and tasteless. Preparations vary in their rate and degree of absorption from the GI tract. The best absorbed is the estolate ester, which results in a peak serum concentration of approximately 4 mcg/mL. The ethylsuccinate and stearate preparations produce peak serum concentrations that range from 0.4 to 1.9 mcg/mL when given at a dose equivalent to the ester. Erythromycin is distributed throughout the body and persists in tissue longer than in the blood. Therapeutic concentrations are reached in middle ear fluid, paranasal sinuses, tonsils, and pleural fluid but not the CSF, even when the meninges are inflamed. Limited data suggest that entry into synovial fluid is poor.

Erythromycin's route of elimination is not clear. A small percentage of a dose of erythromycin can be found in the urine, and erythromycin is known to be concentrated in and excreted with bile. However, most of an administered dose cannot be recovered.

### Side Effects

The most common side effect of erythromycin is GI upset characterized by abdominal pain, nausea, vomiting, or diarrhea. Erythromycin is actually used primarily to promote GI motility in some adults. Allergic reactions occur but are relatively uncommon. Cholestatic hepatitis occurs after treatment with the estolate ester but can be seen with any of the preparations. This side effect has been seen primarily in adults. The better absorption characteristics of the estolate preparation of erythromycin probably outweigh the slight risk for cholestatic hepatitis in children.

### Use

Erythromycin has a broad range of antibacterial activity and is the drug of choice for infections caused by *Mycoplasma pneumoniae*, *Legionella* species, *Corynebacterium diphtheriae*, *Bordetella pertussis*, *Chlamydia trachomatis*, and *Campylobacter jejuni*. Erythromycin is an alternative drug for the treatment of streptococcal and staphylococcal infections and as prophylaxis for syphilis, urinary tract infections, rheumatic fever, and bacterial endocarditis. Macrolide-resistant *S. pyogenes* have been reported in the United States. However, exactly how this discovery may affect the use of this class of drugs for penicillin-allergic individuals with streptococcal pharyngitis is unknown.

The MIC<sub>95</sub> of erythromycin required to inhibit bacteria reported as susceptible by disk is 0.5 mcg/mL or less. Lactobionate and gluceptate preparations are available for parenteral administration but are not used often. The peak serum concentration after intravenous administration is approximately equal to that achieved when estolate is given by mouth.

### Clarithromycin

#### Pharmacologic Properties

Clarithromycin is stable in gastric acid and is well absorbed from the GI tract; furthermore, its bioavailability is not affected by food. A peak serum concentration of 4 to 5 mcg/mL is reached in 2½ to 3 hours, and concentrations in middle ear fluid and lung tissue exceed serum concentrations. The major route of excretion is in bile, but approximately one-third of an administered dose can be recovered in the urine. A metabolite of clarithromycin, 14-hydroxycarithromycin, achieves a serum concentration that is approximately 60% that of clarithromycin and is approximately twice as active against *H. influenzae*.

### Side Effects

Clarithromycin causes much less gastric upset than erythromycin, but diarrhea (6% of cases), vomiting (6%), abdominal pain (3%), and nausea (1%) are the most common side effects. Children frequently complain that the suspension is unpalatable and leaves an unpleasant aftertaste.

### Use

Clinical trials have demonstrated the efficacy of clarithromycin in the treatment of otitis media, pharyngitis, skin and soft tissue infections, *Mycobacterium avium* complex (MAC) infections, and *Helicobacter pylori* infections. In general, clarithromycin can be used for infections traditionally treated with erythromycin. Because of the activity of its 14-hydroxycarithromycin-breakdown product, clarithromycin may prove useful in *H. influenzae* infections.

### Azithromycin

Azithromycin differs structurally from erythromycin and clarithromycin by having a 15-member rather than a 14-member ring. Because of its unique structure, azithromycin has a much larger volume of distribution, a longer half-life, and greater penetration at the cellular level than erythromycin and clarithromycin. In vitro studies show equivalent antimicrobial activity for gram-positive cocci and atypical pathogens, including *Mycoplasma*. Azithromycin is more effective against *H. influenzae* than erythromycin or clarithromycin. Because of its volume of distribution and longer half-life, once-daily dosing is appropriate, and short-course therapy for streptococcal pharyngitis (ie, 5 days) is recommended. Given its prolonged tissue half-life and concentration-dependent killing, azithromycin has been used with shorter courses and less frequent dosing. Newer preparations such as Tri-pak or Zmax use higher doses, given for 3 days or as a single dose, respectively. These preparations are not available for use in children.

The macrolide antibiotics may interact with other drugs by inducing cytochrome P-450. Commonly used drugs that may interact include theophylline, zidovudine, cimetidine, and most anticonvulsants. Because azithromycin does not induce formation of cytochrome P-450, drug-to-drug interactions do not occur with this formulation.

### Clindamycin

#### Mechanism of Action

Clindamycin shares binding sites with erythromycin and chloramphenicol on the 50S ribosomal subunit and interferes with protein synthesis by inhibiting the transpeptidation reaction.

#### Mechanisms of Resistance

The mechanism of bacterial resistance involves modification of the ribosomal binding site, similar to that seen in erythromycin. Clindamycin, however, is not captured or excreted by the macrolide efflux pump, a significant difference from the macrolides.

#### Pharmacologic Properties

Clindamycin is usually given orally, but preparations for intramuscular and intravenous administration are available. Approximately 90% of a dose of clindamycin is absorbed after oral administration, and peak serum concentrations are reached in 1 hour and are dose dependent. Clindamycin palmitate (oral suspension) and clindamycin phosphate (preparation for intravenous administration) are inactive but are hydrolyzed rapidly in vivo to the active free base. Clindamycin is well distributed throughout the body

except for the CSF. Clindamycin is one of the few antimicrobial agents that is concentrated in polymorphonuclear neutrophils. The serum half-life of clindamycin is approximately 2 hours, 24 minutes. Most clindamycin is metabolized in the liver to products that have variable antibacterial activity. Antibacterial activity in the bile and GI tract is very high and results in a dramatic decline in sensitive bowel flora.

### Side Effects

The most highly publicized complication of clindamycin is colitis caused by the toxin of *Clostridium difficile* (pseudomembranous colitis). This complication has now been associated with many other antimicrobial agents and seems to occur less often in children than in adults. Side effects of clindamycin include allergic reactions, rashes, and minor elevations in transaminase concentrations.

### Use

Clindamycin is highly active against most gram-positive aerobic bacteria and most anaerobic bacteria. The major clinical use of clindamycin is the treatment of anaerobic infections. Clindamycin is used routinely when fecal material spills into the abdomen, and it is also used to treat anaerobic bronchopulmonary infections. When used for the treatment of intraabdominal infections, it is generally given along with an aminoglycoside. Clindamycin is also used as alternate therapy for groups A and B streptococcal infections. Group A streptococci that are resistant to macrolides are almost invariably susceptible to clindamycin. It has also been used as oral therapy to complete a course of antibiotics for *S aureus* osteomyelitis. Under these circumstances, clindamycin is an especially attractive alternative in patients who are allergic to  $\beta$ -lactams. In the United States, many strains of penicillin-resistant *S pneumoniae* remain susceptible to clindamycin. Clindamycin is a preferred agent for the treatment of mild-to-moderate community-associated MRSA infections. However, resistance to clindamycin for this indication is rapidly increasing and varies from location to location. Given the explosive increase in clindamycin use, a significant increase in resistance recently has been noted for MRSA. In contrast to TMP-SMX, clindamycin will provide coverage for both staphylococci and streptococci. Providing such coverage may be necessary before culture and sensitivity data are available. Clindamycin does not enter the CSF in useful concentrations. A peak serum concentration of 2.5 to 3.6 mcg/mL is achieved approximately 1 hour after oral administration, and a concentration of 6 to 9 mcg/mL can be reached after intravenous infusion. The MIC<sub>95</sub> of clindamycin for bacteria reported as susceptible by disk is 0.5 mcg/mL or less.

## Chloramphenicol

### Mechanism of Action

Similar to erythromycin and clindamycin, chloramphenicol binds to the 50S ribosomal subunit and inhibits protein synthesis.

### Bacterial Resistance

Mechanisms of resistance include bacterial production of an acetyltransferase that inactivates chloramphenicol and inability of chloramphenicol to enter bacteria.

## Pharmacologic Properties

Chloramphenicol can be given orally as the free base or as chloramphenicol palmitate, which is hydrolyzed in the intestine to free base. Because chloramphenicol is extremely bitter, oral palmitate suspension is given to patients who cannot take capsules containing free base. The intravenous preparation is chloramphenicol succinate, which is also hydrolyzed to free base. Because the palmitate is hydrolyzed more completely than the succinate, its peak serum concentration is generally higher after oral administration. Chloramphenicol distributes well throughout the body, including the brain and CSF. Chloramphenicol is conjugated by the liver and excreted in an inactive form in urine.

### Side Effects

The major side effects of chloramphenicol are dose-related bone marrow suppression, which is reversible; aplastic anemia, which is idiosyncratic and usually fatal; and gray-infant syndrome. Gray-infant syndrome was first described and occurs most commonly in infants, but it has been reported in all age groups. The syndrome, which is characterized by cyanosis, circulatory collapse, and death, occurs when the chloramphenicol concentration becomes very high.

### Use

The importance of chloramphenicol in the treatment of infectious diseases has waxed and waned since its introduction in the late 1940s. Because of its side effects, physicians have tended to use alternate antimicrobial agents whenever possible. However, because of its antibacterial and pharmacologic properties, it must be often included to optimize treatment. With the introduction of the third-generation cephalosporins, use of chloramphenicol in the United States has declined sharply. Formerly, chloramphenicol frequently was considered the drug of choice to treat brain abscesses, bacterial meningitis in infants and children older than 2 months, typhoid fever, and salmonellosis. Currently, metronidazole frequently is selected for anaerobic coverage in brain abscesses, ceftriaxone or cefotaxime for bacterial meningitis, and either TMP-SMX or ceftriaxone to treat typhoid fever and salmonellosis. Although chloramphenicol, rather than tetracycline, was considered by many to be the drug of choice for rickettsial infections in children younger than 8 years, experts continue to consider tetracyclines to be the drug of choice for children who have rickettsial disease or ehrlichiosis regardless of their age. Chloramphenicol frequently is active against vancomycin-resistant enterococci and is frequently included in regimens to treat such infections.

When chloramphenicol must be used, the peak serum concentration should be measured after 4 or 5 doses to ensure that the concentration is safe and therapeutic and that the drug is not accumulating in the patient. A complete blood count and differential count should be done twice a week while the patient is receiving chloramphenicol to check for dose-related bone marrow suppression. The peak serum concentration is reached 1 to 2 hours after oral or intravenous administration and averages 25 mcg/mL orally

and 19 mcg/mL intravenously. The serum half-life of chloramphenicol is approximately 4 hours. The MIC<sub>95</sub> of chloramphenicol for bacteria reported as susceptible by disk is 4 mcg/mL or less for *H influenzae* and 12.5 mcg/mL or less for other organisms. Although chloramphenicol is bactericidal for *H influenzae*, *S pneumoniae*, and *N meningitidis*, it is bacteriostatic for most other bacteria. When used with a  $\beta$ -lactam to treat organisms inhibited only by chloramphenicol, antagonism may occur.

## Tetracycline

### Mechanism of Action

Tetracycline binds to the 30S ribosomal subunit and blocks aminoacyl-tRNA binding to the receptor site; this action inhibits protein synthesis.

### Bacterial Resistance

The entry of tetracycline into bacterial cells is energy dependent; resistance is usually based on interference with entry into the cell. In general, tetracycline is not altered by resistant bacteria.

### Pharmacologic Properties

Several analogs of tetracycline have been produced, but the range of antibacterial activity is similar for each. The semisynthetic analogs, minocycline and doxycycline, are the most active tetracyclines but are used less often than other tetracyclines because they are considerably more expensive.

Tetracycline has a broad spectrum of activity that includes inhibition of *Streptococcus* species, *S aureus* including many MRSA, *Neisseria* species, *E coli*, and many common anaerobic bacteria. Tetracyclines are well absorbed from the intestinal tract, and the peak serum concentration is achieved 1 to 3 hours after oral administration. Tetracycline distributes in varying concentrations throughout most of the body, with concentrations in synovial fluid, urine, and the maxillary sinuses approaching the serum concentration, whereas the CSF concentration reaches only 10% to 20% of the serum concentration.

### Side Effects

The side effects of tetracycline essentially preclude its use in children younger than 8 years and in pregnant women. Tetracycline causes a permanent gray-brown to yellowish discoloration of the teeth and can be associated with hypoplasia of the enamel. Skeletal growth can be depressed when the drug is given to premature infants. Although bone and tooth defects are associated with the total dose of tetracycline given and occur more often after repeated courses, avoiding use of the drug during pregnancy and in young children is prudent. Although these side effects generally preclude the use of tetracycline in children younger than 8 years, for rickettsial diseases and ehrlichiosis, some experts continue to consider doxycycline the drug of choice because the usual duration of therapy is only 7 to 10 days, and staining of teeth is related to the total dose received. Doxycycline is less likely to stain teeth than other tetracyclines. In addition, tetracyclines are effective against rickettsial diseases and

ehrlichiosis, but chloramphenicol may not be. Other side effects of tetracycline are allergic reactions and skin toxicity.

### Use

For individuals older than 8 years, tetracycline is considered the drug of choice for brucellosis, chlamydial infections, lymphogranuloma venereum, epididymitis, granuloma inguinale, infections with spirochetes (Lyme disease, relapsing fever, leptospirosis), pelvic inflammatory disease, plague, prostatitis, and rickettsial infections. Tetracycline is also an effective alternate drug for many other infectious diseases.

In adults, the peak serum concentrations after oral administration of 500 mg of tetracycline or 200 mg of doxycycline or minocycline are 4 mcg/mL, 2.5 mcg/mL, and 2.5 mcg/mL, respectively. The peak serum concentration is reached 1 to 3 hours after administration. The serum half-life of tetracycline is 8 hours, compared with 16 hours for minocycline and 18 hours for doxycycline. Intravenous administration of tetracycline results in a peak serum concentration about twice that achieved when the same dose is given by mouth. The MIC<sub>95</sub> of tetracycline for bacteria reported as susceptible by disk is 4 mcg/mL or less.

## Vancomycin

### Mechanism of Action

Vancomycin inhibits cell wall synthesis during the second stage by inhibiting formation of peptidoglycan. This action is in contrast to  $\beta$ -lactams that inhibit cell wall synthesis during the final stage by binding to the PBPs, which are enzymes that are crucial to the formation of the cell wall.

### Bacterial Resistance

Currently, vancomycin demonstrates good activity against most gram-positive cocci. However, vancomycin-resistant enterococci have become more common. In addition, vancomycin failures caused by infections with staphylococcal strains demonstrating in vitro susceptibility and the emergence of strains with reduced susceptibility to vancomycin have been a source of concern.

Until safer, more rapidly bactericidal agents are available for use in children, several principles must be considered to ensure appropriate use of vancomycin with regard to concerns of emerging resistance. First, although monitoring vancomycin levels has been reserved exclusively for selected patients such as those with altered renal function, monitoring levels now may apparently be the best predictor of clinical outcome, as discussed later. In addition, the physician must be aware that current disk diffusion methods may not adequately recognize vancomycin-intermediate *S aureus*, heteroresistant vancomycin-intermediate strains, or even vancomycin-resistant *S aureus*.

### Pharmacologic Properties

Vancomycin is absorbed minimally after oral administration and is given orally only to treat pseudomembranous colitis caused by the toxin of *C difficile*. Most experts prefer to use metronidazole for this indication

because increased use of vancomycin has been associated with a marked increase in resistance of commonly encountered gram-positive organisms. After intravenous administration, vancomycin is distributed throughout the body, except for the aqueous humor of the eye and the CSF when the meninges are not inflamed. A bactericidal concentration can be achieved in the CSF in cases of meningitis caused by susceptible organisms. Sometimes, vancomycin must be administered intraventricularly to adequately treat meningitis with or without ventriculitis. Vancomycin is excreted unchanged in the urine by glomerular filtration. Therefore monitoring the serum concentration and adjusting the dose based on renal function are important in certain circumstances. (See Side Effects.)

### Side Effects

When vancomycin initially became available for clinical use, commercial preparations contained as much as 20% of another substance, and its use was limited because of its toxicity. Currently available preparations are more highly purified and less toxic. The most common side effects are fever, chills, and pain at the injection site or, less often, flushing and tingling of the face, neck, and thorax (red neck syndrome). These side effects can be prevented largely by infusing vancomycin slowly in a large volume of fluid and by pretreating the patient with an antihistamine before the first dose. Reports of ototoxicity and nephrotoxicity caused solely by vancomycin have been difficult to confirm. Furthermore, the relationship of toxicity to serum concentrations remains controversial. In children, ototoxicity and nephrotoxicity are apparently uncommon, and no clear correlation between serum concentrations and toxicity has been proved.

### Use

In recent years, infections caused by MRSA, coagulase-negative staphylococci (eg, *Staphylococcus epidermidis*), and ampicillin-resistant enterococci have become major indications for the use of vancomycin as the drug of choice. Vancomycin is active against most aerobic gram-positive cocci, including most *Streptococcus* species and *L monocytogenes* and, in combination with streptomycin or gentamicin, is synergistic against enterococci. Many anaerobic streptococci also are susceptible to vancomycin, whereas most gram-negative bacteria are resistant. Some methicillin-resistant staphylococci have demonstrated tolerance to vancomycin killing, and rifampin or TMP-SMX must be added to kill bacteria. Vancomycin is the drug of choice to treat serious infections with methicillin-resistant staphylococci or coagulase-negative staphylococci and to treat enterococcal endocarditis in patients allergic to penicillin. Patients who have staphylococcal infections that are methicillin susceptible might be treated with an antistaphylococcal penicillin. Patients who have bacterial endocarditis caused by *S aureus* have been observed to clear their bacteremia slowly when treated with vancomycin compared with using an antistaphylococcal penicillin in patients whose strain was methicillin sensitive. The initial dose of vancomycin should be a full therapeutic dose, even in patients in renal failure.

Children with serious or invasive disease because of MRSA should receive vancomycin at a dose of 15 mg/kg/dose given every 6 hours. Monitoring trough concentrations is probably the most accurate guide for using vancomycin, and monitoring peak levels is not recommended. Monitoring trough concentrations is generally recommended for those patients with severe infections, patients with fluctuating renal status or volume of distribution, and patients who are morbidly obese. Improved outcomes have been seen in some adult patients with serious MRSA infections in whom trough concentrations of 15 to 20 mcg/mL are maintained. Although efficacy and safety of trough levels in the 15- to 20-mcg/mL range has not been established in children, such troughs should be considered in pediatric patients with serious infections such as bacteremia, endocarditis, osteomyelitis, meningitis, pneumonia, and severe skin and skin structure infections.

### Metronidazole

#### Mechanism of Action

After being taken up by bacteria, metronidazole is reduced to intermediate products that are toxic to the bacteria; the organism then releases inactive end products.

#### Bacterial Resistance

Resistance to metronidazole develops infrequently and has been associated with decreased entry of the drug into bacteria and a decreased rate of reduction when in bacterial cells.

#### Pharmacologic Properties

Metronidazole is active against most anaerobic bacteria, *Treponema pallidum*, *H pylori*, *Campylobacter fetus*, *Gardnerella vaginalis*, *Actinobacillus* species, *Actinomycetem comitans*, *Capnocytophaga* species, and *Trichomonas vaginalis*, as well as certain parasites. After oral administration, metronidazole is absorbed rapidly and completely, with the peak serum concentration being proportional to the dose administered. Metronidazole is distributed well throughout the body, including the CNS and the aqueous humor of the eyes. The serum half-life is approximately 8 hours. After being metabolized, metronidazole is excreted primarily in the urine.

#### Side Effects

The most common side effect of metronidazole is GI upset. Metronidazole also has been associated with CNS dysfunction (seizures, encephalopathy, ataxia) and peripheral neuropathy, and it can potentiate the effects of warfarin and cause a disulfiram reaction when alcohol is consumed. A major concern with the use of metronidazole has been its carcinogenic potential. Although rats and mice that have received metronidazole for a long period have shown an increase in neoplasms, mutagenicity for human cells has not been demonstrated in vitro, and follow-up studies on women who received metronidazole for trichomonal infections have shown that they did not have an increased frequency of tumors up to 10 years later.

### Use

Originally introduced to treat *T vaginalis*, metronidazole also has proved to be effective in the treatment of amebiasis and giardiasis. More recently, it has gained widespread use in the treatment of anaerobic bacterial infections; it is not effective in treating actinomycosis or *Propionibacterium acnes* infections. Metronidazole also is not optimally effective in the treatment of anaerobic lower respiratory tract infections, perhaps because of the presence of aerobic bacteria; the outcome generally is good if penicillin or ampicillin is given concomitantly.

The peak serum concentration achieved in adults after 0.5 g of metronidazole is given orally averages 11.5 mcg/mL; after an intravenous dose of 0.5 g, the serum concentration ranges from 20 to 25 mcg/mL. The MIC<sub>95</sub> of metronidazole for susceptible bacteria usually is 4 mcg/mL or less. Most diagnostic microbiology laboratories do not test anaerobic bacteria routinely for susceptibility.

### Rifampin

#### Mechanism of Action

Rifampin works by inhibiting DNA-dependent RNA polymerase at the  $\beta$  subunit, preventing chain initiation but not elongation.

#### Bacterial Resistance

Bacterial resistance to rifampin develops rapidly by mutation of the DNA-dependent RNA polymerase. The rates of mutation are so high that they preclude use of rifampin as monotherapy except for very short courses of prophylaxis.

#### Pharmacologic Properties

Rifampin is usually administered orally and is completely and rapidly absorbed, with the peak serum concentration achieved 1 to 4 hours after ingestion. An intravenous form of rifampin is also available. Rifampin is distributed throughout the body, deacetylated by the liver, and excreted in the bile. The serum half-life is 2 to 5 hours early in therapy, but it declines over time because of increased biliary excretion. Rifampin also can enter phagocytes and kill viable intracellular organisms, which may explain why rifampin is better able to enter and sterilize abscesses than are other antimicrobial agents.

#### Side Effects

When rifampin is given daily, the most common side effects are a mild and self-limited rash, mild GI complaints, and hepatotoxicity, especially when used in combination with isoniazid. When rifampin is used intermittently at high individual doses, an influenza-like syndrome with fever, aches, and chills develops in up to 20% of patients. Because rifampin crosses the placenta and teratogenic effects have been observed in rodents, it should not be used during pregnancy except in severe cases of tuberculosis. Patients or parents should be warned that urine, feces, saliva, and tears may turn a red-orange color while they are taking the drug. The patient should not wear contact lenses while taking rifampin therapy because the lenses can become permanently discolored.

### Use

Rifampin is extremely active against a wide range of organisms. Most strains of *S aureus* and coagulase-negative staphylococci are exquisitely sensitive to rifampin, which is also active against most other gram-positive cocci. *H influenzae*, *N meningitidis*, and *N gonorrhoeae* are exquisitely susceptible to rifampin, but other aerobic gram-negative pathogens are less so. Rifampin also is active against *Legionella* species and *Mycobacterium tuberculosis*.

Despite its widespread use for treating tuberculosis and as prophylaxis for *N meningitidis* and *H influenzae*, no pediatric preparation of rifampin is available. Instructions for preparing a suspension for pediatric use are detailed in the *Physicians' Desk Reference*. Results from a single study of pediatric patients 6 to 58 months of age, who received 10 mg/kg of rifampin suspended in syrup or as dry powder suspended in applesauce, are also provided. Internationally, rifampin is used most commonly to treat tuberculosis and leprosy. Rifampin also is recommended for prophylaxis of close contacts of patients who have meningococcal disease and for household contacts of children who have systemic *H influenzae* type b disease. When rifampin is used for the last 4 days along with a 10-day course of penicillin-amoxicillin for the treatment of group A  $\beta$ -hemolytic streptococcal infections, the microbiologic failure rate falls to almost zero. Rifampin in combination with other antistaphylococcal agents has been used to treat severe staphylococcal infections such as *S aureus* endocarditis, osteomyelitis, and CSF shunt infections caused by coagulase-negative staphylococci.

The peak serum concentration of rifampin after oral administration of 600 mg to an adult or 10 mg/kg to a child averages 7 mcg/mL. Because of the long half-life of rifampin, the peak serum concentration and bioavailability are better if the drug is given once a day. The MIC<sub>95</sub> of bacteria reported as susceptible by disk to rifampin is 1 mcg/mL or less.

## INITIAL THERAPY OF SELECTED ACUTE INFECTIONS

In most clinical situations, the physician must decide which antimicrobial agent or agents to use before the offending organism has been positively identified through culture results, serologic tests, or microscopic examination of material obtained from the infected site. The physician should consider the following points before starting treatment:

- Patient's age and immune status
- Whether concomitant disease is a factor
- Patient's history of exposure to infectious agents
- Current or recent administration of antimicrobial agents
- Findings on physical examination

Appropriate specimens for bacterial and viral cultures and specimens for serologic tests and microscopic examinations should be obtained before antimicrobial therapy is started, and specific adjunctive, supportive therapy should be instituted concomitantly. Table 60-3 lists the most likely offending organisms and the antimicrobial agent or agents that might be

**Table 60-3** Initial Empirical Therapy for Selected Infections<sup>a</sup>

CLINICAL DIAGNOSIS	MOST LIKELY OFFENDING ORGANISMS	ANTIMICROBIAL AGENTS
Meningitis	Neonate: group B streptococci, <i>E coli</i> , <i>L monocytogenes</i> Child: <i>S pneumoniae</i> , <i>N meningitidis</i> , <i>H influenzae</i> type b	Ampicillin and cefotaxime (or ceftriaxone)  Ceftriaxone or cefotaxime (plus vancomycin if <i>S pneumoniae</i> is suggested)
Brain abscess	Streptococcal species, anaerobes, <i>S aureus</i>	Penicillin and metronidazole (plus nafcillin or vancomycin <sup>b</sup> if <i>S aureus</i> is suggested [plus cefotaxime or ceftriaxone if gram-negative bacilli are suggested])
Orbital cellulitis	Streptococcal species, <i>S aureus</i> , <i>H influenzae</i> type b	Ceftriaxone or cefotaxime plus clindamycin or nafcillin. Vancomycin would be suggested if life-threatening MRSA infection is suggested. <sup>a</sup>
Epiglottitis	<i>H influenzae</i> type b	Ceftriaxone or cefotaxime
Pneumonia (lobar or segmental)	Neonate: group B streptococci, <i>S aureus</i> , gram-negative organisms Child: <i>S pneumoniae</i> , <i>H influenzae</i> type b, <i>S aureus</i> , <i>S pyogenes</i> , <i>M pneumoniae</i>	Ampicillin plus an aminoglycoside (plus vancomycin if MRSA is considered) Penicillin, amoxicillin, amoxicillin-clavulanate, nafcillin (vancomycin or clindamycin if MRSA considered), <sup>b</sup> or erythromycin
Infective endocarditis	<i>Streptococcus viridans</i> , <i>S aureus</i>	Nafcillin (vancomycin if MRSA considered), <sup>b</sup> and an aminoglycoside
Acute diarrhea (fecal white blood cells present)	<i>Salmonella</i> , <i>Shigella</i> species	If patient is systemically ill, very young, or immunocompromised, cefotaxime or ceftriaxone
Abdominal sepsis	Anaerobes, aerobic enterics, enterococci	Carbapenem, $\beta$ -lactam- $\beta$ -lactamase inhibitor (Unasyn and Timentin), advanced-generation cephalosporin with metronidazole
Urinary tract infection	Acute: <i>E coli</i> , <i>Klebsiella</i> species  Chronic: <i>E coli</i> , <i>Proteus</i> species, <i>Pseudomonas</i> species	Gentamicin or trimethoprim-sulfamethoxazole (TMP-SMX) Await culture and sensitivity results
Osteomyelitis	Neonate: group B streptococci, <i>S aureus</i> , <i>S pyogenes</i> , <i>S pneumoniae</i> Child: <i>S aureus</i> , <i>S pyogenes</i>	Nafcillin (vancomycin if MRSA considered) <sup>b</sup> and an aminoglycoside Nafcillin (clindamycin or vancomycin if MRSA considered) <sup>b</sup>
Pyogenic arthritis	Neonate: group B streptococci, <i>S aureus</i> , <i>S pyogenes</i> , <i>N gonorrhoeae</i>  Child: <i>H influenzae</i> type b (<5 yr), <i>S aureus</i> , <i>S pyogenes</i> , <i>N gonorrhoeae</i>	Nafcillin (clindamycin or vancomycin if MRSA considered) <sup>b</sup> and an aminoglycoside (or cefotaxime) Ceftriaxone or cefotaxime (test MIC for <i>S aureus</i> ) plus nafcillin <sup>b</sup>
Suspected sepsis	Neonate: group B streptococci, <i>L monocytogenes</i> , gram-negative enteric organisms Infant (1–6 wk): as for neonate plus as for child Child: <i>S pneumoniae</i> , <i>H influenzae</i> type b, <i>N meningitidis</i>	Ampicillin and an aminoglycoside (or cefotaxime) Ampicillin and ceftriaxone  Ceftriaxone
<b>COMPROMISED HOST</b>		
Fever only	<i>S aureus</i> , <i>E coli</i> , <i>Pseudomonas</i> species	Cefipime or antipseudomonal extended-spectrum penicillin
Shock (sepsis without source)	Neonate: group B streptococci, enterics  Child: <i>N meningitidis</i> , <i>S pneumoniae</i>	Ampicillin and an aminoglycoside (substitute vancomycin for ampicillin if <i>S aureus</i> considered) Ceftriaxone or cefotaxime (substitute vancomycin if MRSA is considered)

<sup>a</sup>For most clinical diagnoses, an acceptable alternative choice of antibiotics might be proposed.<sup>b</sup>If local prevalence of methicillin-resistant *Staphylococcus aureus* is high, then vancomycin will be empirical drug of choice.

used empirically for various diagnoses under these circumstances. Local susceptibility patterns and other special circumstances always should be considered.

## PROPHYLAXIS

Antimicrobial agents can be given to prevent colonization, to eradicate carriage, to prevent bacteria that colonize one body site from causing disease at a usually sterile site, or to prevent bacteria that have been introduced into a usually sterile site from causing disease. In general, an antimicrobial agent that has the narrowest spectrum that is effective against the most likely pathogen or pathogens should be used at the lowest dose and for the shortest period that will prevent infection. Prophylaxis also should be restricted to situations in which it is known to be effective and in which the risk for infection exceeds the potential risks of the antimicrobial agent or the emergence of resistant bacteria. Recommendations for preoperative antimicrobial prophylaxis are listed in Table 60-4, and clinical situations in which prophylactic antimicrobial agents might be effective and the recommended regimens for prophylaxis are listed in Table 60-5. The *Red Book: Report of*

*the Committee on Infectious Diseases* (American Academy of Pediatrics) has updated dose recommendations for specific antimicrobials in specific situations.

## ANTIMICROBIAL THERAPY FOR VIRAL, FUNGAL, AND PARASITIC INFECTIONS

Currently, only a limited number of agents and a limited number of indications are available for systemic treatment of viral, fungal, and parasitic infections in the United States; most primary care pediatricians are unlikely to be familiar with the use of these agents. Therefore, the pediatrician should consult a specialist in pediatric infectious diseases before treating a patient with these drugs. The antiviral drugs available currently, along with their indications and dosages, are presented in Table 60-6; antifungal drugs (their route of administration, dosages, and adverse reactions) are listed in Table 60-7. Treatment of parasitic infections is discussed in Chapter 308, Parasitic Infections, in the *AAP Red Book*, in *Nelson's Pediatric Antimicrobial Therapy*, and in the *Medical Letter Handbook of Antimicrobial Therapy*.

**Table 60-4**

**Recommendations for Preoperative Antimicrobial Prophylaxis<sup>a</sup>**

OPERATION	LIKELY PATHOGENS	RECOMMENDED DRUGS	PREOPERATIVE DOSE
<b>Neonatal</b> ( $\leq 72$ h of age)—all major procedures	Group B streptococci, enteric gram-negative bacilli, <sup>b</sup> enterococci, coagulase-negative Staphylococci	Ampicillin <b>PLUS</b> Gentamicin	50 mg/kg  2.5 mg/kg
<b>Neonatal</b> ( $> 72$ h of age)—all major procedures	Prophylaxis targeted to colonizing organisms, nosocomial organisms, and operative site		
<b>Cardiac</b> (cardiac surgical procedures, prosthetic valve or pacemaker, ventricular assist devices)	<i>Staphylococcus epidermidis</i> , <i>Staphylococcus aureus</i> , <i>Corynebacterium</i> species, enteric gram-negative bacilli <sup>b</sup>	Cefazolin <b>OR</b> (if MRSA or MRSE is likely) <sup>a</sup> Vancomycin	30 mg/kg  15 mg/kg
<b>GASTROINTESTINAL</b>			
Esophageal and gastroduodenal	Enteric gram-negative bacilli, <sup>b</sup> gram-positive cocci	Cefazolin (high risk only) <sup>c</sup>	30 mg/kg
Biliary tract	Enteric gram-negative bacilli, <sup>b</sup> enterococci,	Cefazolin <sup>d</sup>	30 mg/kg
Colorectal or appendectomy (uncomplicated, nonperforated)	Enteric gram-negative bacilli, <sup>b</sup> enterococci, anaerobes ( <i>Bacteroides</i> species) <sup>e</sup>	Cefoxitin <b>OR</b> Metronidazole <b>PLUS</b> Gentamicin <b>OR</b> Cefazolin <b>PLUS</b> Metronidazole <b>OR</b> Clindamycin <b>PLUS</b> Gentamicin <b>OR</b> Ciprofloxacin	40 mg/kg  15 mg/kg  2.5 mg/kg  30 mg/kg  15 mg/kg  10 mg/kg  2.5 mg/kg (gentamicin); 10 mg/kg (ciprofloxacin)

*Continued*

**Table 60-4** Recommendations for Preoperative Antimicrobial Prophylaxis<sup>a</sup>—cont'd

OPERATION	LIKELY PATHOGENS	RECOMMENDED DRUGS	PREOPERATIVE DOSE
Ruptured viscus (treatment, not prophylaxis)	Enteric gram-negative bacilli, <sup>b</sup> enterococci anaerobes ( <i>Bacteroides</i> species) <sup>c</sup>	Cefoxitin <b>WITH OR WITHOUT</b> Gentamicin <b>OR</b> Gentamicin <b>PLUS</b> Metronidazole <b>PLUS</b> Ampicillin <b>OR</b> Meropenem <b>OR</b> Other regimens for complicated appendicitis <sup>f</sup>	40 mg/kg 2 mg/kg 2.5 mg/kg 10 mg/kg 50 mg/kg 20 mg/kg
Genitourinary	Enteric gram-negative bacilli, <sup>b</sup> enterococci	Ampicillin <b>PLUS</b> Gentamicin <b>OR</b> Cefazolin	50 mg/kg 2 mg/kg (gentamicin); 30 mg/kg (cefazolin)
<b>Head and neck surgery</b> (incision through oral or pharyngeal mucosa)	Anaerobes, enteric gram-negative bacilli, <sup>b</sup> <i>S aureus</i>	Clindamycin <b>WITH OR WITHOUT</b> Gentamicin <b>OR</b> Cefazolin <b>PLUS</b> Metronidazole Cefazolin	10 mg/kg 2.5 mg/kg 30 mg/kg 15 mg/kg 30 mg/kg
<b>Neurosurgery</b> (craniotomy, intrathecal baclofen shunt or ventricular shunt placement)	<i>S epidermidis</i> , <i>S aureus</i>	<b>OR</b> (if MRSA or MRSE is likely) <sup>a</sup> Vancomycin	15 mg/kg
<b>Ophthalmic</b>	<i>S epidermidis</i> , <i>S aureus</i> , streptococci, enteric gram-negative bacilli <sup>b</sup> <i>Pseudomonas</i> species	Gentamicin, ciprofloxacin, ofloxacin, moxifloxacin, tobramycin <b>OR</b> Neomycin-gramicidin-polymyxin B <b>OR</b> Cefazolin Cefazolin <b>OR</b> (if MRSA or MRSE is likely) <sup>a</sup> Vancomycin	Multiple drops topically for 2–24 h before procedure Multiple drops topically for 2–24 h before procedure 100 mg, subconjunctivally 30 mg/kg 15 mg/kg
<b>Orthopedic</b> (internal fixation of fractures, implantation of materials including prosthetic joint and spinal procedures with and without instrumentation)	<i>S epidermidis</i> , <i>S aureus</i>	Cefazolin Cefazolin <b>OR</b> (if MRSA or MRSE is likely) <sup>a</sup> Vancomycin	30 mg/kg 30 mg/kg 15 mg/kg
<b>Thoracic</b> (noncardiac)	<i>S epidermidis</i> , <i>S aureus</i> , streptococci, gram-negative enteric bacilli <sup>b</sup>	Cefazolin <b>OR</b> (if MRSA or MRSE is likely) <sup>a</sup> Vancomycin	30 mg/kg 15 mg/kg
Traumatic wound (nonbites)	<i>S aureus</i> , group A streptococci, <i>Clostridium</i> species	Cefazolin	30 mg/kg

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *S epidermidis*.

**Table 60-5** Regimens for Antimicrobial Prophylaxis for a Dental Procedure

SITUATION	AGENT	REGIMEN: SINGLE DOSE 30 TO 60 MIN BEFORE PROCEDURE	
		CHILDREN	ADULTS
Oral	Amoxicillin	50 mg/kg	2 g
Unable to take oral medication	Ampicillin	50 mg/kg, IM or IV	2 g, IM or IV
	<b>OR</b>		
	Cefazolin or ceftriaxone	30 mg/kg, IM or IV (cefazolin); 50 mg/kg, IM or IV (ceftriaxone)	1 g, IM or IV
Allergic to penicillins or oral ampicillin	Cephalexin <sup>a,b</sup>	50 mg/kg	2 g
	<b>OR</b>		
	Clindamycin	10 mg/kg	900 mg
	<b>OR</b>		
	Azithromycin or clarithromycin	15 mg/kg	500 mg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone <sup>b</sup>	30 mg/kg, IM or IV (cefazolin); 50 mg/kg, IM or IV (ceftriaxone)	1 g, IM or IV
	<b>OR</b>		
	Clindamycin	10 mg/kg, IM or IV	900 mg, IM or IV

IM, intramuscular; IV, intravenous.

From American Academy of Pediatrics. Prevention of bacterial endocarditis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015: 970–971.

<sup>a</sup>Or other first- or second-generation oral cephalosporin in equivalent pediatric or adult dosage.

<sup>b</sup>Cephalosporins should not be used in a person with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

**Table 60-6** Non-HIV Antiviral Drugs<sup>a</sup>

GENERIC (TRADE NAME)	INDICATION	ROUTE	AGE	USUALLY RECOMMENDED DOSAGE
Acyclovir <sup>b,c,d,e</sup> (Zovirax)	Neonatal herpes simplex virus (HSV) infection	IV	Birth to 3 mo	Treatment dosing: 60 mg/kg per day, in 3 divided doses for 14–21 days
		PO	2 wk to 8 mo	Suppressive dosing following completion of treatment dosing: 300 mg/m <sup>2</sup> , 3 times per day for 6 months
	HSV encephalitis	IV	≥3 mo to 12 y	30–45 mg/kg per day, in 3 divided doses for 14–21 days; FDA-approved dose for this indication and age range is 60 mg/kg per day, in 3 divided doses, but nephrotoxicity may be increased at this higher dose <sup>f</sup>
		IV	≥12 y	30 mg/kg per day, in 3 divided doses for 14–21 days
	Varicella in immunocompetent host <sup>g</sup>	Oral	≥2 y	≤40 kg: 80 mg/kg per day, in 4 divided doses for 5 days; maximum daily dose, 3,200 mg/day >40 kg: 3,200 mg, in 4 divided doses for 5 days
		IV	≥2 y	30 mg/kg per day for 7–10 days or 1,500 mg/m <sup>2</sup> per day in 3 doses for 7–10 days
	Varicella in immunocompetent host requiring hospitalization	IV	≥2 y	30 mg/kg per day for 7–10 days or 1,500 mg/m <sup>2</sup> per day in 3 doses for 7–10 days
	Varicella in immunocompromised host	IV	<1 y	30 mg/kg per day, in 3 divided doses for 7–10 days
		IV	≥1 y	1,500 mg/m <sup>2</sup> per day, in 3 doses for 7–10 days; some experts recommend the 30 mg/kg per day dose

Continued

**Table 60-6** Non-HIV Antiviral Drugs<sup>a</sup>—cont'd

GENERIC (TRADE NAME)	INDICATION	ROUTE	AGE	USUALLY RECOMMENDED DOSAGE
	Zoster in immunocompetent host	IV (if requiring hospitalization) Oral	All ages ≥12 y	Same as for varicella in immunocompromised host 4,000 mg/day, in 5 divided doses for 5–7 days
	Zoster in immunocompromised host	IV IV	<12 y ≥12 y	30 mg/kg per day, in 3 divided doses, for 7–10 days 30 mg/kg per day, in 3 divided doses, for 7–10 days
	HSV infection in immunocompromised host (localized, progressive, or disseminated)	IV Oral	All ages ≥2 y	30 mg/kg per day, in 3 divided doses for 7–14 days 1,000 mg/day, in 3–5 divided doses for 7–14 days
	Prophylaxis of HSV in immunocompromised hosts who are HSV seropositive	Oral IV	≥2 y All ages	600–1,000 mg/day, in 3–5 divided doses during period of risk 15 mg/kg, in 3 divided doses during period of risk
	Genital HSV infection: first episode	Oral  IV	≥12 y  ≥12 y	1,000–1,200 mg/day, in 3–5 divided doses for 7–10 days. Oral pediatric dose: 40–80 mg/kg per day, divided in 3–4 doses for 5–10 days (maximum 1.0 g/day) 15 mg/kg per day, in 3 divided doses for 5–7 days
	Genital HSV infection: recurrence	Oral	≥12 y	1,000 mg in 5 divided doses for 5 days, or 1,600 mg in 2 divided doses for 5 days, or 2400 mg in 3 divided doses for 2 days
	Chronic suppressive therapy for recurrent genital and cutaneous (ocular) HSV episodes	Oral	≥12 y	800 mg/day, in 2 divided doses for as long as 12 continuous mo
Adefovir (Hepsera)	Chronic hepatitis B	Oral	≥12 y	10 mg, once daily, in patients with adequate renal function; optimal duration of therapy unknown
Amantadine (Symmetrel) <sup>h</sup>	Influenza A: treatment and prophylaxis (see Influenza, p 476) <sup>h</sup>	Oral  Oral	1–9 y  ≥10 y	Treatment or prophylaxis: 5 mg/kg per day, maximum 150 mg/day, in 2 divided doses Treatment or prophylaxis: <40 kg: 5 mg/kg per day, in 2 divided doses; ≥40 kg: 200 mg/day, in 2 divided doses
Boceprevir (Victrelis)	Chronic hepatitis C	Oral	Dose by weight, not age Adult dose (≥18 years) <sup>i</sup>	Alternative prophylactic dose for children >20 kg and adults: 100 mg/day 800 mg, 3 times per day for 24–44 wk in combination with pegylated interferon alfa and ribavirin for 28–48 wk of total treatment, depending on prior HCV treatment status and HCV viral load during therapy Initiate therapy with pegylated interferon and ribavirin for 4 wk prior to initiating boceprevir
Cidofovir (Vistide)	Cytomegalovirus (CMV) retinitis	IV	Adult dose <sup>i</sup>	Induction: 5 mg/kg, once weekly, × 2 doses with probenecid and hydration Maintenance: 5 mg/kg, once every 2 wk, with probenecid and hydration

**Table 60-6** Non-HIV Antiviral Drugs<sup>a</sup>—cont'd

GENERIC (TRADE NAME)	INDICATION	ROUTE	AGE	USUALLY RECOMMENDED DOSAGE
Entecavir (Baraclude)	Chronic hepatitis B	Oral	≥16 y <sup>i</sup>	0.5 mg, once daily, in patients who have not received prior nucleoside therapy; 1 mg once daily in patients who are previously treated (not first choice in this setting); optimum duration of therapy unknown
Famciclovir (Famvir)	Genital HSV infection, episodic recurrent episodes	Oral	Adult dose <sup>i</sup>	Immunocompetent: 2,000 mg/day, in 2 divided doses for 1 day HIV-infected patients: 1,000 mg, in 2 divided doses for 7 days
	Daily suppressive therapy	Oral	Adult dose <sup>i</sup>	Immunocompetent: 500 mg/day, in 2 divided doses for 1 y, then reassess for recurrence of HSV infection
	Recurrent herpes labialis	Oral	Adult dose <sup>i</sup>	Immunocompetent: 1,500 mg as a single dose HIV-infected patients: 1,000 mg/day, in 2 divided doses for 7 days
	Herpes zoster	Oral	Adult dose <sup>i</sup>	1,500 mg/day, in 3 divided doses for 7 days
Foscarnet <sup>b</sup> (Foscavir)	CMV retinitis in patients with acquired immunodeficiency syndrome	IV	Adult dose <sup>i</sup>	180 mg/kg per day, in 2–3 divided doses for 14–21 days, then 90–120 mg/kg once a day as maintenance dose
	HSV infection resistant to acyclovir in immunocompromised host	IV	Adult dose <sup>i</sup>	80–120 mg/kg per day, in 2–3 divided doses until infection resolves
	VZV infection resistant to acyclovir	IV	Adult dose <sup>i</sup>	120 mg/kg per day, divided every 8 h, up to 3 wk
Ganciclovir <sup>b</sup> (Cytovene)	Symptomatic congenital CMV disease	IV	Birth to 2 mo	12 mg/kg per day, divided every 12 h; duration of treatment is 6 months, but most or all of the treatment should be accomplished with oral valganciclovir (see below)
	Acquired CMV retinitis in immunocompromised host <sup>i</sup>	IV	Adult dose <sup>i</sup>	Treatment: 10 mg/kg per day, in 2 divided doses for 14–21 days; Long-term suppression: 5 mg/kg per day for 7 days/wk or 6 mg/kg per day for 5 days/wk
	Prophylaxis of CMV in high-risk host	IV	Adult dose <sup>i</sup>	10 mg/kg per day, in 2 divided doses for 1–2 wk, then 5 mg/kg per day, in 1 dose for 100 days or 6 mg/kg per day for 5 days/wk
Interferon alfa-2b (Intron A)	Chronic hepatitis B	SC	1–18 y >18 y	6 million IU/m <sup>2</sup> , 3 times/wk for 16–24 wk 5 million IU/day; or 10 million IU, 3 times/wk, for 16 wk
	Chronic hepatitis C	SC; IM	>18 y <sup>i</sup>	3 million IU, 3 times/wk, for 24–48 wk, depending on HCV genotype Note: pegylated interferon preferred over interferon alfa-2b
Lamivudine (Epivir-HBV)	Treatment of chronic hepatitis B	Oral	≥2 y	3 mg/kg once day (maximum 100 mg/day) (children coinfecting with HIV and hepatitis B should use the approved dose for HIV)
Oseltamivir <sup>k</sup> (Tamiflu)	Influenza A and B: treatment (see Influenza, p 476)	Oral	Birth to <9 mo <sup>l</sup>	3 mg/kg, twice daily for 5 days <sup>l</sup>
		Oral	9–12 mo	3.5 mg/kg, twice daily for 5 days

Continued

**Table 60-6** Non-HIV Antiviral Drugs<sup>a</sup>—cont'd

GENERIC (TRADE NAME)	INDICATION	ROUTE	AGE	USUALLY RECOMMENDED DOSAGE
		Oral	1–12 y	≤15 kg: 30 mg, twice daily; 15.1–23 kg: 45 mg, twice daily; 23.1–40 kg: 60 mg, twice daily; >40 kg: 75 mg, twice daily for 5 days
	Influenza A and B: prophylaxis	Oral	≥13 y	75 mg, twice daily for 5 days
		Oral	1–12 y	Same as treatment for patients 1–12 y of age, except dose given once daily for 10 days (following known exposure) or for up to 6 wk (preexposure during community outbreak)
		Oral	≥13 y	75 mg once daily for 10 days (following known exposure) or for up to 6 wk (preexposure during community outbreak)
Pegylated interferon alfa-2a (Pegasys)	Chronic hepatitis B	SC	>18 y <sup>i</sup>	180 µg, once weekly for 48 wk
	Chronic hepatitis C	SC	≥23 kg	180 µg/1.73 m <sup>2</sup> , once weekly for 24–48 wk, depending on HCV genotype, given concomitantly with oral ribavirin <sup>m</sup>
	Chronic hepatitis C	SC	>18 y <sup>i</sup>	180 µg, once weekly for 24–48 wk, depending on HCV genotype
Pegylated interferon-alfa-2b (PegIntron)	Chronic hepatitis C	SC	>18 y >3 to 17 y	1.5 µg/kg, once weekly for 24–48 wk, depending on HCV genotype
				60 µg/m <sup>2</sup> , once weekly for 24–48 wk, depending on HCV genotype
Ribavirin (Rebetol or Copegus)	Treatment of hepatitis C in combination with an alfa interferon	Oral/capsule	≥3 y (Note: capsule doses recommended for use with pegylated interferon alfa-2a and alfa-2b are different)	Fixed dose by weight is suggested for 24–48 wk, depending on HCV genotype 23–33 kg: 200 mg am and pm >34–46 kg: 200 mg am and 400 mg pm >47–59 kg: 400 mg am and pm >60–74 kg: 400 mg am and 600 mg pm >75 kg: 600 mg am and pm
		Oral/solution (Rebetol)	≥3 y	15 mg/kg per day, in 2 divided doses for 24–48 wk, depending on HCV genotype
Rimantadine (Flumadine) <sup>h</sup>	Influenza A: treatment <sup>i</sup>	Oral	≥13 y	200 mg/day, in 2 divided doses
	Influenza A: prophylaxis (see Influenza, p 476) <sup>h</sup>	Oral	≥1 y	1–9 y of age: 5 mg/kg per day, maximum 150 mg/day, once daily ≥10 y of age, <40 kg: 5 mg/kg per day, in 2 divided doses; ≥40 kg: 200 mg/day in 2 divided doses
Simeprevir	Chronic hepatitis C	Oral	Adult dose <sup>i</sup>	150 mg, taken once daily with food, as a component of combination therapy with both pegylated interferon alfa and ribavirin
Sofosbuvir	Chronic hepatitis C	Oral	Adult dose <sup>i</sup>	400 mg, taken once daily with or without food, as a component of combination therapy with ribavirin or with ribavirin plus pegylated interferon
Telaprevir	Chronic hepatitis C	Oral	Adult dose <sup>i</sup>	750 mg, 3 times per day for 12 wk in combination with pegylated interferon alfa and ribavirin for 24–48 wk of total treatment, depending on prior HCV treatment status and HCV viral load during therapy
Telbivudine (Tyzeka)	Chronic hepatitis B	Oral	Adult dose <sup>i</sup>	600 mg, once daily

**Table 60-6** Non-HIV Antiviral Drugs<sup>a</sup>—cont'd

GENERIC (TRADE NAME)	INDICATION	ROUTE	AGE	USUALLY RECOMMENDED DOSAGE
Tenofovir (Viread)	Chronic hepatitis B	Oral	>12 y dose	300 mg, once daily
Valacyclovir (Valtrex)	Varicella	Oral	2 to <18 y	20 mg/kg, 3 times daily for 5 days, not to exceed 1 g per dose 3 times daily
	Genital HSV infection, first episode	Oral	Adult dose <sup>i</sup>	2 g/day, in 2 divided doses for 10 days
	Episodic recurrent genital HSV infection	Oral	Adult dose <sup>i</sup>	1 g/day, in 2 divided doses for 3 days
	Daily suppressive therapy for recurrent genital HSV infection	Oral	Adult dose <sup>i</sup>	1,000 mg, once daily for 1 year, then reassess for recurrences
	Recurrent herpes labialis	Oral	>12 y	4 g/day, in 2 divided doses for 1 day
	Herpes zoster	Oral	Adult dose <sup>i</sup>	3 g/day, in 3 divided doses for 7 days
Valganciclovir (Valcyte)	Symptomatic congenital CMV disease	Oral	Birth to 2 mo	32 mg/kg per day, in 2 divided doses for 6 mo
	Acquired CMV retinitis in immunocompromised host	Oral	Adult dose <sup>i</sup>	Treatment: 900 mg, twice daily for 3 wk Long-term suppression: 900 mg, once daily
	Prevention of CMV disease in kidney or heart transplant patients	Oral	4 mo–16 y	Dose once a day within 10 days of transplantation until 100 days post-transplantation according to dosage algorithm based on body surface area and creatinine clearance Dose (mg) = 7 × body surface area × creatinine clearance (see drug package insert)
Zanamivir (Relenza)	Influenza A and B: treatment (see Influenza, p 476)	Inhalation	≥7 y (treatment)	10 mg, twice daily for 5 days
	Influenza A and B: prophylaxis	Inhalation	≥5 y (prophylaxis)	10 mg, once daily for as long as 28 days (community outbreaks) or 10 days (household setting)

FDA, US Food and Drug Administration; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous; SC, subcutaneous; VZV, varicella-zoster virus.

From American Academy of Pediatrics. Non-HIV antiviral drugs. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015: 919–926.

<sup>a</sup>Drugs for human immunodeficiency virus infection are not included. See [aidsinfo.nih.gov](http://aidsinfo.nih.gov) for current information on HIV drugs and treatment recommendations.

<sup>b</sup>Dose should be decreased in patients with impaired renal function.

<sup>c</sup>Oral dosage of acyclovir in children should not exceed 80 mg/kg per day (3,200 mg/day).

<sup>d</sup>Acyclovir doses listed in this table are based on clinical trials and clinical experience and may not be identical to doses approved by the FDA.

<sup>e</sup>In times of shortage of intravenous acyclovir, the American Academy of Pediatrics Committee on Infectious Diseases recommends that existing supplies of intravenous acyclovir be conserved to improve availability for neonatal HSV infections, herpes simplex encephalitis, or HSV and varicella-zoster virus infections in immunocompromised patients, including more ill pregnant women with visceral dissemination of either virus. If acyclovir is not available, intravenous ganciclovir should be substituted. Alternative regimens to the use of intravenous acyclovir and other options for priority and nonpriority conditions are outlined in an exclusive *Red Book Online Intravenous Acyclovir Shortage Table* ([redbook.solutions.aap.org/selfserve/ssPage.aspx?SelfServeContentId=acyclovir-shortage](http://redbook.solutions.aap.org/selfserve/ssPage.aspx?SelfServeContentId=acyclovir-shortage)).

<sup>f</sup>Monitor for nephrotoxicity and neurologic irritation. Consider involving an infectious diseases or pharmacology specialist if weight-based dosing exceeds 800 mg per dose or if being administered with other nephrotoxic medications.

<sup>g</sup>Selective indications; see Varicella-Zoster Infections in AAP *Red Book*.

<sup>h</sup>Since 2005–2006, almost all influenza A (H3N2) strains and 2009 pandemic H1N1 strains tested have been resistant to adamantanes, and adamantane use therefore has not been recommended. See Influenza in AAP *Red Book* for specific recommendations.

<sup>i</sup>There are not sufficient clinical data to identify the appropriate dose for use in children.

<sup>j</sup>Some experts use ganciclovir in immunocompromised hosts with CMV gastrointestinal tract disease and CMV pneumonitis (with or without CMV Immune Globulin Intravenous).

<sup>k</sup>See [www.cdc.gov/flu/professionals/antivirals/index.htm](http://www.cdc.gov/flu/professionals/antivirals/index.htm) for specific recommendations, which may vary on the basis of most recent influenza virus susceptibility patterns.

<sup>l</sup>Preterm, <38 weeks' postmenstrual age, 1.0 mg/kg/dose, orally, twice daily; preterm, 38 through 40 weeks' postmenstrual age, 1.5 mg/kg/dose, orally, twice daily; preterm >40 weeks' postmenstrual age through 8 months' chronologic age, 3.0 mg/kg/dose, orally, twice daily.

<sup>m</sup>See approved product label for PEGASYS (pegylated interferon alfa-2a).

For more information on individual drugs, see *Physician's Desk Reference* or [www.pdr.net](http://www.pdr.net) (for registered users only).

**Table 60-7** Recommended Doses of Parenteral and Oral Antifungal Drugs

DRUG	ROUTE	DOSE (PER DAY)	ADVERSE REACTIONS <sup>a,b</sup>
Amphotericin B deoxycholate (see Antifungal Drugs for Systemic Fungal Infections, p 905, for detailed information)	IV	1.0–1.5 mg/kg per day; infuse as a single dose over 2 h	Fever, chills, gastrointestinal tract symptoms, headache, hypotension, renal dysfunction, hypokalemia, anemia, cardiac arrhythmias, neurotoxicity, anaphylaxis
	IT	0.025 mg, increase to 0.5 mg, twice/wk	Headache, gastrointestinal tract symptoms, arachnoiditis/radiculitis
	IV	5 mg/kg per day, infused over 2 h	Fever, chills, other reactions associated with amphotericin B deoxycholate, but less nephrotoxicity; hepatotoxicity has been reported with lipid complex
Amphotericin B lipid complex (Abelcet) <sup>c,d</sup>	IV	5 mg/kg per day, infused over 2 h	Fever, headache, nausea, vomiting, diarrhea, leukopenia, hepatic enzyme elevations, and phlebitis
Anidulafungin <sup>c,d</sup>	IV	Adults: 100–200 mg loading dose, then 50–100 mg once daily (higher dose for candidemia) Children: load with 1.5 to 3 mg/kg once, then 0.75–1.5 mg/kg per day	Fever, chills, other reactions associated with amphotericin B, but less nephrotoxicity; hepatotoxicity has been reported
Liposomal amphotericin B (AmBisome) <sup>c,d</sup>	IV	3–5 mg/kg, infused over 1–2 h	Fever, rash, pruritus, phlebitis, headache, gastrointestinal tract symptoms, anemia; concomitant use with cyclosporine is not recommended unless potential benefits outweigh potential risks
Caspofungin <sup>c,d</sup>	IV	Adults: 70 mg loading dose, then 50 mg once daily Children: 70 mg/m <sup>2</sup> loading dose, then 50 mg/m <sup>2</sup> once daily	Gastrointestinal tract symptoms, hepatotoxicity
Clotrimazole	PO	10-mg tablet, 5 times per day (dissolved slowly in mouth)	Rash, gastrointestinal tract symptoms, hepatotoxicity, Stevens-Johnson syndrome, anaphylaxis
Fluconazole <sup>b,d</sup>	IV	Children: 3–6 mg/kg per day, single dose (up to 12 mg/kg per day for serious infections)	
	PO	Children: 6 mg/kg once, then 3 mg/kg per day for oropharyngeal or esophageal candidiasis; 6–12 mg/kg per day for invasive fungal infections; 6 mg/kg per day for suppressive therapy in HIV-infected children with cryptococcal meningitis Adults: 200 mg once, followed by 100 mg/day for oropharyngeal or esophageal candidiasis; 400–800 mg/day for other invasive fungal infections; 400 mg/day for suppressive therapy in HIV-infected patients with cryptococcal meningitis	
Flucytosine	PO	50–150 mg/kg per day in 4 doses at 6-h intervals (adjust dose if renal dysfunction); follow trough levels closely	Bone marrow suppression, renal dysfunction, gastrointestinal tract symptoms, rash, neuropathy, hepatotoxicity, confusion, hallucinations
Griseofulvin	PO	Ultramicrosize: 5–15 mg/kg, single dose; maximum dose, 750 mg Microsize: 10–20 mg/kg per day divided in 2 doses; maximum dose, 1000 mg	Rash, paresthesias, leukopenia, gastrointestinal tract symptoms, proteinuria, hepatotoxicity, mental confusion, headache
Itraconazole <sup>b,d</sup>	IV, PO	Children: 5–10 mg/kg per day divided into 2 doses; confirm therapeutic trough level after 2 wk of therapy to ensure adequate drug exposure ( $\geq 1$ $\mu$ g/mL but $< 10$ $\mu$ g/mL) Adults: 200–400 mg/day once or twice a day; 200 mg, once a day, for suppressive therapy in HIV-infected patients with histoplasmosis	Gastrointestinal tract symptoms, rash, edema, headache, hypokalemia, hepatotoxicity, thrombocytopenia, leukopenia; cardiac toxicity is possible in patients also taking terfenadine or astemizole

**Table 60-7** Recommended Doses of Parenteral and Oral Antifungal Drugs—cont'd

DRUG	ROUTE	DOSE (PER DAY)	ADVERSE REACTIONS <sup>a,b</sup>
Ketoconazole <sup>b,d</sup>	PO	Children <sup>e</sup> : 3.3–6.6 mg/kg per day, single dose Adults: 200 mg, twice a day for 4 doses, then 200 mg, once a day	Hepatotoxicity, gastrointestinal tract symptoms, rash, anaphylaxis, thrombocytopenia, hemolytic anemia, gynecostasia, adrenal insufficiency; cardiac toxicity is possible in patients also taking terfenadine or astemizole
Micafungin <sup>c,d</sup>	IV	Adults: 50–150 mg once daily Children: 2–10 mg/kg per day once daily (higher dose needed for patients <8 y of age), maximum 200 mg per day	Fever, headache, nausea, vomiting, diarrhea, leukopenia, hepatic enzyme elevations, and phlebitis
Nystatin	PO	Infants: 200,000 U, 4 times a day, after meals Children and adults: 400,000–600,000 U, 3 times a day, after meals	Gastrointestinal tract symptoms, rash
Posaconazole <sup>c,d</sup>	PO	Adults: 400 mg, 2 times a day with fatty meals (or liquid nutritional supplement) for treatment; 200 mg, 3 times a day for prophylaxis Children: not known	Gastrointestinal tract symptoms, rash, edema, headache, anemia, neutropenia, thrombocytopenia, fatigue, arthralgia, myalgia, fever
Terbinafine <sup>c</sup>	PO	Adults: 250 mg, once a day Children: <20 kg: 67.5 mg/day; 20–40 kg: 125 mg/day; >40 kg: 250 mg/day	Gastrointestinal tract symptoms, rash, taste abnormalities, cholestatic hepatitis
Voriconazole <sup>d</sup>	IV	Children 2–12 y: 9 mg/kg, IV, every 12 h for 1 day, then 8 mg/kg, IV, every 12 h (maximum dose, 350 mg, every 12 h); follow trough levels closely (>2 µg/mL) Adults and children ≥12 y: 6 mg/kg, every 12 h for 1 day (loading dose), then 4 mg/kg, every 12 h; follow trough levels closely (>1 µg/mL)	Visual disturbance, hallucinations, photosensitive rash, increased liver function tests, encephalopathy; recent reports of aggressive cutaneous malignancy associated with prolonged voriconazole use
	PO	Children 2–12 y: 9 mg/kg, every 12 h; follow trough levels closely (much lower bioavailability in children than adults) Adults: <40 kg: 200 mg, every 12 h for 1 day, then 100 mg, every 12 h; >40 kg: 400 mg, every 12 h for 1 day, then 200–300 mg, every 12 h	

HIV, human immunodeficiency virus; IT, intrathecal; IV, intravenous; PO, oral.

## Chapter 61

# PSYCHOSOCIAL THERAPIES

W. Douglas Tynan, PhD; Meghan McAuliffe Lines, PhD

This chapter first provides an overview of the evidence-based nonpharmacologic treatments available for the common mental health disorders of childhood. In the parlance of the mental health community, they may be called *psychotherapy* or simply *therapy*. Here they will be called *psychosocial treatments*. These treatments may be delivered by a variety of mental health professionals (eg, licensed clinical psychologists, social workers, professional counselors, marriage and family therapists, child psychiatrists) trained in the specific techniques of that therapy. Interactive Web-based programs show promise as additional or alternative sources of these therapies.

Second, the chapter draws from these evidence-based psychosocial treatments those common elements that are effective across a number of disorders and potentially applicable to the treatment of children with emerging or undifferentiated symptoms, as they might present in the primary care setting. Practical resources are offered to support physicians in applying these common elements to the care of these children, to children referred for and awaiting care in the mental health specialty system, and to children for whom the appropriate mental health specialty resources are inaccessible.

## HISTORY

The origin of modern psychotherapy with children is usually attributed to the pioneering work of Sigmund Freud at the turn of the 20th century. Freud's ideas about the importance of early childhood experiences and his publication of case studies with both adults and children framed the field, and his influence is still evident. Although these psychoanalytic and psychodynamic concepts date back more than 100 years, behavioral therapy concepts arose soon after, early in the 20th century, in the work on conditioning and learning by Mary Cover Jones and JB Watson, based on Pavlovian conditioning models of learned fears and maladaptive emotional responses. Both psychodynamic and learning theory approaches focused on early traumatic experiences as causal to later behavioral problems, but current approaches to etiology are more complex. It is generally accepted that variations in behavior may have origins in temperamental differences, early patterns of attachment, parent-child interaction difficulties, and social factors, along with early traumatic experience. Work arose on behavioral interventions based both on early Pavlovian theories of learned emotional responses and BF Skinner's writings in the mid-20th century on positive operant conditioning and learning of voluntary responses to improve behaviors. This launched a variety of behavioral approaches, ranging from early reward systems to providing parents and teachers with strategies for

positively oriented behavior modification. During the same era, various play therapies, dramatic therapies, and relationship therapies emerged as additional strategies to help ameliorate children's emotional and behavioral problems. As more was learned about multiple etiologic factors of childhood disorders, multiple therapy approaches were developed to address those factors. By the start of the 21st century, Alan Kazdin identified 551 differently named psychosocial treatment approaches that are used with children. This is a vast number that does not even include eclectic approaches to treatment, in which elements of several therapies are combined, which is the approach most commonly used by physicians.

Clearly, the practice of psychotherapy grew much more quickly than research into its effectiveness. However, in the past decade, research has emphasized documenting the critical elements of therapeutic approaches in treatment manuals and then testing these treatment modalities in representative patients. This research of manualized therapy using written reminders of specific approaches has revealed common elements of effective therapy. More important, these therapies specify what behavior changes need to occur for true treatment progress to be achieved. The American Academy of Pediatrics (AAP) Task Force on Mental Health used the common elements of effective treatment as the basis for the guidance it provided to primary care physicians for the initial management of mental health problems. Within the mental health professions, the concept of modular therapies has been developed, which involves determining elements that have been proven effective in treating specific disorders and then, for individual patients, combining elements drawn from different therapy approaches to address the specific set of symptoms presented. Thus, for a child demonstrating both anxiety and oppositional behavior, elements of evidence-based cognitive behavioral therapy to manage the anxiety and parent training to address the oppositional behavior would be implemented. Chorpita and Daleiden have developed a model including training and treatment monitoring using this modular approach.

## INTERNALIZING VERSUS EXTERNALIZING BEHAVIOR DISORDERS IN CHILDREN

Because all psychosocial disorders are not the same, it is critically important to identify the key symptoms for which children typically present for treatment, to systematically research effective therapeutic strategies. The most commonly diagnosed emotional and behavioral disorders of childhood can be largely divided into 2 broad categories—externalizing disorders and internalizing disorders. Externalizing behavior refers to the group of disorders that are manifested in children's display of negative outward behavior, including aggression, oppositionality, defiance, delinquency, and hyperactivity. Children with these disorders are frequently noncompliant, have difficulty following rules, are restless, and are overly active. The most common referrals for psychotherapy, making up 50% to 75% of all children referred, are for disruptive

behavior problems. The diagnoses that typically fall into this category are attention-deficit/hyperactivity disorder, oppositional defiant disorder, conduct disorder, bipolar disorder, and disruptive behavior disorder not otherwise specified (NOS).

In contrast, internalizing disorders in children represent the group of emotional disorders in which the symptoms primarily affect a child's internal psychological environment. Rather than acting out, children with internalizing disorders often display anxious, depressed, withdrawn, or inhibited behavior. Anxiety disorders are among the most common forms of psychopathology in children and adolescents. Specific internalizing disorders that may emerge in childhood include anxiety disorders (eg, separation anxiety disorder, generalized anxiety disorder, specific phobia, obsessive-compulsive disorder, anxiety disorder NOS) and depressive disorders (eg, major depressive disorder, depressive disorder NOS).

It is noteworthy that although the distinction between the categories of internalizing and externalizing disorders is important for case conceptualization, treatment decisions, and research, these disorders are not necessarily mutually exclusive. In fact, there is often significant comorbidity between externalizing and internalizing disorders in children. However, research on evidence-based treatments for childhood disorders has demonstrated that the most effective types of treatment differ based on the type of problem. A helpful illustration can be seen in Table 61-1, Evidence-Based Child and Adolescent Psychosocial Interventions, which was originally developed by the Hawaii Department of Health and included in the AAP CD-ROM *Addressing Mental Health Concerns in Primary Care: A Clinician's Toolkit*. This resource demonstrates the particular psychosocial interventions that are most and least helpful for the various categories of child emotional and behavioral difficulties based on a summary of the research in the field. In the case of children who seem to be exhibiting symptoms of both internalizing and externalizing difficulties, a best practice recommendation is to treat the primary symptoms first (ie, symptoms that are causing the most significant impairment).

## PSYCHOSOCIAL TREATMENT FOR EXTERNALIZING DISORDERS IN CHILDREN

### Parent Management Training

An evidence-based treatment for a school-aged child diagnosed with both attention-deficit/hyperactivity disorder and oppositional defiant disorder may include guidance for parents on behavior management and medication for the impulsivity and lack of focus.

Of the therapies used, parent management training (PMT), a therapeutic technique centered around teaching parents to modify their child's behavior through the use of evidence-based strategies, has been proved effective for disruptive behavior in a variety of settings and methods of implementation. PMT is a term that encompasses a number of evidence-based programs. All PMT programs that have been

**Table 61-1** Evidence-Based Child and Adolescent Psychosocial Interventions

	<b>PROBLEM AREA</b>	<b>LEVEL 1: BEST SUPPORT</b>	<b>LEVEL 2: GOOD SUPPORT</b>	<b>LEVEL 3: MODERATE SUPPORT</b>	<b>LEVEL 4: MINIMAL SUPPORT</b>	<b>LEVEL 5: NO SUPPORT<sup>a</sup></b>
<b>INTERNALIZING DISORDERS</b>	Anxious or avoidant behaviors	Cognitive behavioral therapy (CBT), CBT and medication, CBT with parents, education, exposure, modeling	Assertiveness training, attention, CBT for child and parent, cultural storytelling, family psychoeduca- tion, hypnosis, relaxation, stress inoculation	Contingency management, group therapy	Biofeedback, CBT with parents only, play therapy, psychody- namic therapy, rational emotive therapy, social Skills	Assessment/monitoring, attachment therapy, client- centered therapy, eye movement desensitization and reprocessing (EMDR), peer pairing, psychoeducation, relationship counseling, teacher psychoeducation Life skills, play therapy, psychodynamic therapy, psychoeducation, social skills
	Depressive and withdrawn behaviors	CBT, CBT and medication, CBT with parents, family therapy	Client-centered therapy, cognitive behavioral psychoeducation, expressive writing/ journaling/diary, interpersonal therapy, relaxation	None	Problem solving, self-control training, self-modeling	
<b>EXTERNALIZING DISORDERS</b>	Delinquency and disrupt- ive behavior	Anger control, assertiveness training, CBT, contingency management, multisystemic therapy, parent management training, parent management training and problem solving, social skills	CBT and teacher training, communica- tion skills, functional family therapy, parent management training and CBT, parent management training and classroom management, prob- lem solving, rational emotive therapy, relaxation, self-control training, therapeutic foster care, transactional analysis	Client-centered therapy, family therapy, moral reasoning training, outreach counseling, peer pairing	CBT and teacher psy- choeducation, parent management training and classroom management and CBT, parent management training and self-verbalization, physical exercise, stress inoculation	Behavioral family therapy, catharsis, CBT with parents, collaborative problem solving, education, exposure, family empowerment and support, family systems therapy, group therapy (!!), imagery training, parent management training and peer support, play therapy, psychodynamic therapy, self-verbalization, skill development, wraparound

<sup>a</sup>Level 5 refers to treatments whose tests were unresponsive or inconclusive. The symbol (!!) indicates that at least 1 study found negative effects on the main outcome measure. The risk for using treatments so designated should be weighed against potential benefits. Excerpted from PracticeWise Evidence-Based Child and Adolescent Psychosocial Interventions. Reprinted with permission from PracticeWise. For updates and an explanation of PracticeWise determination of evidence level, please visit [www.aap.org/mentalhealth](http://www.aap.org/mentalhealth).

proved effective include all 6 of the following components:

1. **Increasing positive interaction between parent and child through the use of special playtime strategies.** This approach is found in all evidence-based PMT programs and is also common to many other therapies designed to encourage positive parent-child interaction, including Greenspan's Developmental, Individual Differences, and Relationship-based Floortime model, and Brazelton's Touchpoints. For parents who are frustrated with constant arguments and battles with their children, reestablishing a positive relationship is an essential first step.
2. **Teaching parents how to record and monitor behavior accurately.** Change comes with learning, which can be enhanced and accelerated by teaching parents reinforcement and reward skills, but it still requires some time to change patterns of behavior. Parents often respond emotionally in the heat of the moment. It is only when they document and track gradual change that they can maintain their own efforts to bring about change.
3. **The use of reinforcement and rewards to increase the rate of desirable behaviors.** Although parents often present with their list of problem behaviors, they usually have lost sight of what they want their children to do instead. Identifying the desired positive behaviors and using social rewards such as praise, hugs, and more time with parents help reinforce positive behaviors quickly and can change the overall tone of the parent-child relationship.
4. **Teaching parents how to give directions and commands that are effective.** One of the difficulties noted in observational studies of parents and children in conflict is the difficulty some parents have in recognizing what children can comprehend and in simply giving clear, direct, understandable commands. This component, although brief in most programs, is essential.
5. **Coaching and training in the use of mild, non-physical punishments such as time-out to reduce undesirable behaviors.** Research shows that parents use physical punishment inconsistently and that their use of time-out, loss of privileges, or contingent work chores is more effective and less emotionally damaging to the parent-child relationship. This is also in line with current AAP policy on disciplining children.
6. **All of the skills are taught within a context of typical child development for age.** Parents often overestimate their child's abilities, skills, and motivation and require information on typical child development. Thus, effective PMT programs either include specific information about developmental skills or are designed for very specific age ranges. Although various effective programs may place a different emphasis on specific skills, all effective programs implement the complete set of all 6 elements in discussion, role-playing, and the use of video or active coaching to teach parents new behavior patterns. Programs use a variety of strategies, including intensive individual coaching

(Parent-Child Interaction Therapy, Helping the Noncompliant Child), group format with video (Incredible Years), and variations of group and individual family formats (PMT—Oregon Model, Triple P—Positive Parenting Program), as well as these strategies in combination with other therapeutic interventions (Problem Solving Skills + PMT).

## PSYCHOSOCIAL TREATMENT FOR INTERNALIZING DISORDERS IN CHILDREN

### Cognitive Behavioral Therapy

Internalizing disorders in children, encompassing the anxious and depressive disorders, comprise the second core group of psychosocial difficulties that often lead to referrals for mental health treatment. Across diagnostic categories, cognitive behavioral therapy (CBT) has consistently received the best support for reducing internalizing symptoms in children. Although the primary approach for addressing externalizing behavior in children is to provide parents with skills to shape the child's behavior through modifying the environment, research has demonstrated that, for internalizing symptoms, it is critical to address the child's thoughts, feelings, and behaviors directly.

The specific treatment strategies vary by treatment program, but a number of common components are present across CBT programs. According to Phil Kendall, the primary components of all CBT programs are strategies designed to address changes in thinking, feeling, and behavior, as well as an enactive component. CBT programs for children with internalizing difficulties typically address the following:

1. **Cognitions.** Children with anxiety and depression often have faulty cognitions, including distorted thinking about themselves and the world around them and negative, automatic thoughts that cause them to feel fearful or distressed. One aspect of CBT is to help children learn to identify these cognitions and cope with or even change them.
2. **Feelings.** Another important aspect of CBT is to help children learn affective recognition and coping strategies for unpleasant emotions.
3. **Behavior.** Behavioral strategies typically used in CBT include coping skills to help children manage some of their distressing emotional experiences. Behavioral strategies might include relaxation techniques, scheduling of pleasurable activities, and problem-solving strategies.
4. **Practice.** A key element of CBT is opportunities to practice new strategies and evaluate them. Although internalizing disorders are, by definition, manifested in symptoms that are within the child, it is important to consider the social context and provide opportunities for social practice with new strategies. Research has demonstrated that these components can be effectively delivered in individual or group settings.

An example of a well-supported CBT program for anxiety in children is the Coping Cat program. In Coping Cat, children learn to recognize the physiologic and cognitive symptoms of anxiety, learn cognitive

and behavioral strategies for coping with the anxiety, and practice the skills taught.

CBT programs have been developed for the treatment of depression in youth as well. One example includes the TAKING ACTION program, in which children learn to identify emotions, learn coping skills for unpleasant emotions, learn problem-solving strategies, and learn to restructure negative cognitions. This treatment is performed in a group setting, providing opportunities to practice.

For CBT to be an effective treatment strategy, the child must have the cognitive capacity to engage in the treatment. Studies indicate that school-aged children (typically developing children aged 7 years and older) are able to benefit, provided that they have adequate language skills. The therapy requires being able to label emotions, use language to develop an action plan, and use language to evaluate success.

### Common Elements of Evidence-Based Psychosocial Treatments

One of the criticisms of evidenced-based approaches is that they have been developed in randomized controlled trials (RCTs), for single disorders, and often come with a lengthy, detailed manual that leads the therapist and patient through a stepwise series of goals in a specific course of treatment, often for a fixed number of sessions. Clinical practice, however, is marked by comorbidity of more than 1 diagnosis and requires some flexibility in implementation to match the needs of the family. In practice, often the approach is to have the family successfully complete one goal before moving on to the next, and the goal is often determined by immediate need. Thus, a therapist working from an evidence-based perspective needs the elements of each approach available in a modular format that can be presented in the order needed by the patient. The common elements approach is best captured in the PracticeWise program, which incorporates evidence-based approaches to treating anxiety, depression, trauma, and conduct problems in a single set of treatment modules. Included in this program are descriptions of the disorders and detailed guidelines for therapists to guide sessions, as well as handouts for patients and their parents on identifying emotions, problem-solving and cognitive strategies for managing depression and anxiety, and the common elements of PMT (described previously). This program is a comprehensive approach to using modules shown to be effective so that a therapist can construct a treatment approach individualized for each child's particular set of symptoms.

### TREATMENTS LACKING A RESEARCH EVIDENCE BASE

One of the hallmarks of the therapies cited as evidence based are manualized therapies. This kind of systematic approach, which lends itself to standardization across patients, is more easily studied in an RCT than more individualized treatments like play therapy, various creative arts therapies, and individualized psychotherapy. These latter kinds of approaches lend themselves to analysis on a case-by-case, N-of-1, or

anecdotal basis. In some circumstances, the RCT is not an appropriate research method—and highly individualized therapy (eg, treatment individualized to a patient rather than following a manual) is among those circumstances. As a result, a number of therapies show promise with some patients but have no specific evidence regarding their effectiveness. In some situations, therapy can result in harm or worsening of the condition. As with any other type of treatment, there can be iatrogenic effects.

Along with providing information about the treatment methods with the greatest support, a second benefit of recent outcomes research is to provide guidance about which forms of treatment do not work well, or may even potentially cause harm. Across disorders, at this time, there is little to no research support for the use of play therapy or psychodynamic therapy with children, and there is no support for eye movement desensitization and reprocessing.

Mode of treatment delivery can also influence outcomes. CBT and some other treatment modalities addressing anxiety and depression are effective in a group setting. However, research has demonstrated that for children with disruptive oppositional and defiant behavior disorders, some types of group therapy are potentially harmful. A review and study showed that unstructured groups for conduct-disordered adolescents tended to increase deviant and oppositional behavior. More structured groups for children with disruptive behavior that have specific goals for self-control strategies can result in positive therapeutic effects.

Physicians can help to promote the optimal health and well-being of their patients by providing research-informed guidance to parents when selecting mental health providers and by developing a list of established referrals who practice evidence-based approaches to treatment of child psychosocial problems.

In general, although one-to-one individual unstructured psychotherapy with children is the preferred modality of treatment for many physicians, review of research does not support this form of treatment; statistically, it is no better than no treatment. Active, structured therapies, with clear goals and procedures that involve working with parents (and other involved adults) are most effective in shaping behavior. For children aged 7 years and older who have typical cognitive and language skills, teaching coping skills and strategies with targeted goals is also effective. Indeed, these approaches have a more extensive body of supportive research than other treatment, including many medication treatments. Properly carried out, effective psychosocial treatment has excellent long-term benefits that extend years beyond the termination of treatment and can positively influence a child's overall developmental course.

## Chapter 62

# PSYCHOTROPIC MEDICATIONS IN PRIMARY CARE PEDIATRICS

Mark A. Riddle, MD; Susan dosReis, PhD; Gloria Reeves, MD; Lawrence S. Wissow, MD, MPH; David Pruitt, MD; Jane Meschan Foy, MD

## INTRODUCTION

According to an American Academy of Pediatrics (AAP) survey published in 2008, more than 80% of primary care pediatricians reported that it was their responsibility to identify children with attention-deficit/hyperactivity disorder (ADHD), anxiety, depression,

and substance abuse. Most (70%) also thought it was their responsibility to manage ADHD; however, only about one-fourth thought it was their responsibility to manage anxiety (29%), depression (25%), or substance abuse (21%). In a policy statement published in July 2009, the AAP recommended that primary care pediatricians achieve competence in initiating care not only for children with ADHD, but also for children with anxiety, depression, and substance use or abuse. In addition, the statement recommended that pediatricians achieve competence in providing a medical home for children with the full range of pediatric mental health conditions. Implicit in these recommendations is the necessity for pediatricians to be knowledgeable about pediatric psychopharmacology in general and to use psychotropic medications safely and effectively in certain clinical situations.

The goal of this chapter is to offer a clear, rational, and evidenced-based framework for using psychotropic agents in children with psychiatric diagnoses. Although many pediatricians are already using these medications, there remains a wide variance of comfort with, confidence in, and knowledge about how drugs are initiated, titrated, and monitored across care settings. This chapter, although not a how-to manual, provides a unifying approach grounded in the most up-to-date research, filling in the “who, what, and why” aspects of psychopharmacologic management. The intention is not to dictate practice specifics, but rather to offer a methodologic approach that can best serve a wide range of pediatricians who, after completing a thorough diagnostic assessment in which medication-responsive illness is identified, must then make decisions regarding medication treatment options for children and families.

## GETTING STARTED: PREREQUISITES FOR PRESCRIBING

The safe and effective use of psychiatric medications in the primary care setting requires several conditions, outlined in Box 62-1.

### Determining Whether to Prescribe Medication: The Diagnostic Threshold

An accurate diagnosis of medication-responsive disorders (ie, disorders for which, at a minimum, there is sufficient evidence of a clinically meaningful reduction of symptom severity in response to medication) is important in pediatric psychopharmacology. This diagnostic accuracy ensures that those children who may benefit from medication are offered a trial, and it prevents needless use of medication in children who will not benefit from such treatment. Even with an accurate diagnosis and evidence-based treatments, there is no completely sensitive and specific way to determine which individual child will respond to medication or any other evidence-based therapy for psychiatric disorders, nor is there a way to predict who will experience treatment side effects or what type of side effect may emerge.

The uncertainty underlying these issues presents clinical challenges for the prescribing pediatrician. A relatively simple approach to assessing whether to

### BOX 62-1 Conditions for Safe and Effective Prescribing of Psychotropic Medications by Pediatricians

#### The disorder for which medication is prescribed needs to be

- Sufficiently common to be seen regularly by a pediatrician
- Efficiently and accurately diagnosable by a pediatrician

#### The medication needs to

- Have demonstrated efficacy
- Be relatively safe, as assessed by several parameters
- Have side effects that are reasonably predictable, readily detected, and readily managed

#### The dosing and monitoring of the medication need to

- Follow guidelines that are reasonably established and easily followed
- Include somatic monitoring that is limited to vital signs, height, and weight

#### The prescribing pediatrician needs to have

- Expertise in diagnosing the relevant disorders
- Knowledge of available psychosocial treatments (eg, parent behavior management training, cognitive behavioral therapy)
- Knowledge of the medications prescribed
- Procedures for monitoring medication effects and adherence

#### The system of care needs to provide

- Access to pediatric psychopharmacology expertise for consultation on issues beyond the expertise of the pediatrician
- Adequate payment for services rendered
- Minimal administrative and regulatory barriers

### BOX 62-2 Assessing Whether to Prescribe Medication

1. Does the child have *sufficient* symptoms to support a syndrome or disorder?
2. Have the symptoms been present for a *sufficient* period?
3. Is the child experiencing *sufficient* impairment or distress from the symptoms in ways that negatively affect academic development, family life, interactions with peers, participation in activities, or emotional well-being?
4. Is this disorder *sufficiently* different from normal levels of activity and impulsivity (in contrast with ADHD), worry and concern (in contrast with an anxiety disorder), or demoralization or grief (in contrast with an episode of depression)?
5. Have evidence-based therapies (eg, behavior management training with parents for ADHD; cognitive behavioral therapy for anxiety or depression) been tried, if available?

recommend medication is outlined in Box 62-2. This approach approximates the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* in terms of essential components or criteria and practice guidelines for therapies.

The term *sufficient* (or *sufficiently*) appears in each of the criteria or components in Box 62-2. Thus, the pediatrician must judge whether each of the 4 components of diagnosis—symptoms, duration,

impairment, and non-normality—crosses a diagnostic threshold that warrants a recommendation for medication.

All pediatricians struggle with threshold when deciding on a diagnosis and determining whether to initiate a specific treatment. A familiar example in pediatrics is ADHD: all 18 symptoms of ADHD in the *DSM-5* include the term *often*, but there is no specific definition of *often*. Comparable examples in general medicine of the struggle with threshold include diagnosis and treatment of pain and insomnia.

Parent reports and self-reports can provide useful information about a child's symptoms and their severity and are often useful in determining threshold. Among the many available reporting tools, the following generally incorporate current *DSM* criteria and are available as open access tools: the Vanderbilt Attention-Deficit/Hyperactivity Disorder Rating Scale for parents and teachers CESj-DC; the Screen for Anxiety Related Disorders (SCARED), parent and child versions, for symptoms of anxiety; and the Patient Health Questionnaire-9 (PHQ-9) Modified for Teens (available at [www.thereachinstitute.org/images/GLAD-PCToolkit\\_V2\\_2010.pdf](http://www.thereachinstitute.org/images/GLAD-PCToolkit_V2_2010.pdf)) for symptoms of depression.

Also critical to threshold is assessment of the child's functioning: determination of whether the child's symptoms are causing impairment of school performance, relationships with peers and family members, and progress toward developmental goals. Several pediatrician-friendly tools are available to assist with this assessment, including the impact scale (second page) of the Strengths and Difficulties Questionnaire and the Columbia Impairment Scale. Use of a tool can break ground for a fuller assessment of functioning and serve

as a baseline for monitoring the child's functioning over time.

### Assessing Common Disorders

It is important to recognize that there is a hierarchy of difficulty in making accurate diagnoses of specific psychiatric disorders. Among the disorders addressed in this chapter, ADHD is generally the easiest and most straightforward to diagnose because the symptoms of ADHD are observable by multiple informants (eg, parents, teachers) in multiple settings (eg, school, home). Yet, even ADHD can often be confused with comorbid intellectual, language, and learning difficulties and with anxiety or the effects of trauma.

Anxiety disorders may be more difficult to diagnose than ADHD. Although anxiety and depression are both considered internalizing conditions, most symptoms of anxiety can be observed or easily elicited. Physical symptoms (eg, abdominal pain, muscle tension) are common in children with anxiety and are familiar to pediatricians. Other symptoms, such as avoiding social situations or phobic stimuli or entering the parents' bedroom or bed at night in response to separation concerns, are either reported by the children to their parents or are readily observed by parents. Asking children what they worry about may reveal anxiety more easily than asking, "Do you worry?"

Depression may be difficult to diagnose because demoralization, grief, and adjustment disorder, which are common in children and adolescents, can mimic the symptoms of depression. Parsing depression from these other conditions requires time and patience. When the differential diagnosis is complex, consultation with a child and adolescent psychiatrist may be needed to confirm the diagnosis of the child or adolescent who is suspected of being depressed.

Information about assessment (and treatment) of various psychiatric disorders can be found in other chapters in this volume.

### Screening for Adverse Childhood Experiences and Substance Abuse

Because symptoms of ADHD, anxiety, and depression can result from or be exacerbated by adverse childhood experiences (ACEs), including trauma, it is important to conduct universal screening for ACEs. ACEs may include single incidents (eg, car accident), ongoing traumas (eg, exposure to domestic violence), or a combination of stresses. ACE screening may identify environmental factors that are contributing to a child's mood and behavior and urgent concerns that require safety planning (eg, child abuse reporting). The Adverse Childhood Experiences study, developed by the Centers for Disease Control and Prevention (CDC), is a useful screening tool ([www.cdc.gov/violenceprevention/acestudy](http://www.cdc.gov/violenceprevention/acestudy)).

A simple screening question that can be incorporated into a standard visit is, "Since the last time I saw you, has anything really scary or upsetting happened to you or your family?" For children younger than 8 years, screening optimally relies on parent report, so the analogous question should be asked to parents, "Since the last time I saw your child, has anything really scary or upsetting happened to your child or

anyone in your family?" Ultimately, the clinical relevance of a reported ACE depends on the pediatrician's judgment.

Substance use and experimentation are very common among adolescents. The CDC reports that approximately 25% of high school-aged adolescents report they have bought, sold, or been given drugs on school grounds in the past 6 months ([www.cdc.gov/features/YRBS](http://www.cdc.gov/features/YRBS)). Preteens and adolescents should be screened for substance use. The CRAFFT substance abuse screening questionnaire is a validated brief pediatric screening tool ([www.ceasar-boston.org/clinicians/crafft.php](http://www.ceasar-boston.org/clinicians/crafft.php)).

Substance abuse and post-traumatic stress disorder (PTSD) may co-occur with other mood or behavioral disorders (eg, ADHD and marijuana abuse; depression and PTSD). Complex psychopathology may require further mental health consultation for diagnostic evaluation or incorporation of specific psychosocial treatments. It is important to note that there are no US Food and Drug Administration (FDA)-approved pediatric medication treatments for either substance abuse or PTSD, but there are evidence-based psychosocial interventions.

### Early Determinants of Need for Referral

Children with undiagnosed learning disabilities may also present with significant mood or behavior problems. These problems may be related to school maladjustment (eg, symptoms occur primarily in a school setting, not at home). Parents may benefit from referral to family advocacy programs or support programs available in the school system that can provide information on obtaining learning disabilities evaluations and advocating for disability services.

Finally, children living with complex psychosocial situations (eg, those whose parents have mental health or substance abuse issues, cognitive impairment, or significantly impaired parenting skills or those who have been maltreated or exposed to significant childhood adversities) may need a more thorough evaluation by a mental health professional because symptoms of ADHD, depression, and anxiety may mimic those of other psychiatric disorders. If a parent's mental illness is affecting the child's mental health, referral of the parent for his or her own care is warranted.

### Psychosocial Treatments

Effective, evidence-based psychosocial treatments, often described simply as therapy, are available for many pediatric psychiatric disorders. See reviews by Ginsburg and Weisz for a summary of these therapies and the evidence supporting them, and Chapter 61, Psychosocial Therapies. Psychosocial treatments are often tried before considering medication and are also used in combination with medication. For very young children, guidelines by the American Academy of Child and Adolescent Psychiatry recommend at least 2 trials of psychosocial treatment before starting medication. Evidence from large studies sponsored by the National Institute of Mental Health (NIMH) demonstrate the advantage of combining psychosocial and medication treatment over medication or therapy alone for ADHD (ages 7 to 9 years), common anxiety

disorders (separation anxiety disorder, social phobia, generalized anxiety disorder; ages 7 to 17 years), and depression (ages 12 to 17 years).

It is important to consider when psychosocial interventions are preferred over medication. Many children and adolescents present to pediatricians with mild depression or anxiety (ie, they meet diagnostic criteria, but symptoms and impairment are minimal) or subthreshold depression or anxiety (ie, they do not meet the diagnostic criteria for the disorder). In general, such a child is likely to benefit from a psychosocial intervention and may not need medication.

Despite the clear effectiveness of psychosocial treatments and the pressing need for them, there are still far too few mental health physicians and therapists with the proper training and experience to provide high-quality evidence-based therapy, and families face many administrative and financial barriers to access. For many pediatricians, these factors add pressure to prescribe psychopharmacologic therapy as a single first-line treatment. Pediatricians can join with families and mental health specialists in their community to advocate for evidence-based psychosocial services in both public and private systems of care. Ideally, psychosocial interventions always accompany pharmacologic interventions.

### Off-Label Prescribing

Before the mid-1990s, there were very few psychiatric medications that had been approved by the FDA for pediatric indications (ie, approved for use in children younger than age 18 years). Those approved included stimulants for ADHD, tricyclic antidepressants for enuresis, a few antipsychotics for psychosis, and lithium for mania in bipolar disorder. Thus, to treat psychiatric disorders in children and adolescents, it was often necessary to prescribe off label. Although many medications still lack FDA-approved pediatric indications across the age span, the number of pediatric indications has increased markedly over the past 20 years. This has occurred in response to federal legislation, including the Best Pharmaceuticals for Children Act (BPCA) and the Pediatric Research Equity Act (PREA). Also, the NIMH began funding large, multisite treatment studies in the mid-1990s.

A number of medications are now available with indications for psychiatric disorders in children, including ADHD, depression, obsessive-compulsive disorder (OCD), mania in bipolar disorder, psychosis in schizophrenia, and “irritability” in children with autism. Thus, prescribing off label, especially for a medication that has no indication for any psychiatric disorder in children and adolescents, should be carefully justified and documented in the medical record.

## CONCEPTUAL FRAMEWORK FOR PRESCRIBING PSYCHIATRIC MEDICATIONS

### Overview

According to an expert task force comprising representatives from major international and regional (ie, American, Asian, and European) organizations, led by

the European College of Neuropsychopharmacology (ECNP), there are 108 psychotropic drugs available for prescribing. (The app “Nomenclature” is available at [play.google.com/store/apps/details?id=il.co.inmanage.nomenclature&hl=en](http://play.google.com/store/apps/details?id=il.co.inmanage.nomenclature&hl=en).) Most of these drugs are approved by the FDA for adults in the United States. This large number of medications can be overwhelming, even for experienced mental health specialists.

The goal of the proposed conceptual framework for prescribing psychotropic medications by pediatricians is to simplify and organize these medications into manageable and targeted groups in accordance with the AAP mental health competencies policy statement.

The first and most important group of psychotropic medications for pediatricians (Group 1) includes medications for the common psychiatric disorders: ADHD, major depressive disorder (MDD), and anxiety disorders. The best epidemiologic data indicate that more than 80% of psychotropic medications prescribed to children are for ADHD, anxiety, and depressive disorders.

Group 1 includes all FDA-approved medications for ADHD in children: 2 stimulants (methylphenidate and amphetamine), 2  $\alpha_2$ -adrenergic agonists (guanfacine and clonidine), and 1 norepinephrine reuptake inhibitor (atomoxetine). It also includes all FDA-approved medications for depression in children: the 2 selective serotonin reuptake inhibitors (SSRIs) fluoxetine and escitalopram. There are no FDA-approved medications for children with anxiety. This is, in large part, because of a discrepancy between FDA rules regarding anxiety disorder indications and the efficacy studies that have been conducted in children and adolescents with anxiety. Thus, for anxiety in children, 3 SSRIs are included—fluoxetine, fluvoxamine, and sertraline—that all have 1 high-quality, positive efficacy study for common anxiety disorders and FDA approval for OCD, an anxiety-related condition.

Thus, there are only 9 medications in Group 1 (Table 62-1). It is important to emphasize that these 9 Group 1 medications are not a formulary or restricted list of possible medications. However, as will be described in greater detail later, they are the only medications with high-quality scientific evidence supporting their efficacy. Also, as will be described later, these medications are relatively safe.

The second group of medications (Group 2) includes all FDA-approved medications for children with other disorders (ie, not ADHD, anxiety, or depression). Group 2 includes 5 antipsychotics (aripiprasole, olanzapine, quetiapine, risperidone, and paliperidone) and the mood stabilizer lithium. These medications are approved for treatment of children with psychosis in schizophrenia, mania in bipolar disorder, and, for aripiprasole and risperidone, “irritability” in autism. However, they are most commonly used in children to treat behavioral problems, especially aggression. Group 2 medications have a higher risk profile and are associated with more concerning acute and chronic adverse effects than Group 1 medications. Pediatricians are ideally suited to monitor the adverse effects of Group 2 medications, and some pediatricians, for various reasons, will be involved in prescribing them.

**Table 62-1**      **Group 1 Medications\***

DRUG (MODE OF ACTION)	INDICATION <sup>c</sup>	FDA APPROVAL/APPROVED AGE
<b>ADHD</b>		
Methylphenidate (stimulant)	ADHD	Yes; ≥6
Amphetamine (stimulant) <sup>a</sup>	ADHD	Yes; ≥6
Guanfacine (α-adrenergic agonist)	ADHD	Yes; ≥6
Clonidine (α-adrenergic agonist)	ADHD	Yes; ≥6
Atomoxetine (NRI)	ADHD	Yes; ≥6
<b>CERTAIN ANXIETY DISORDERS<sup>b</sup></b>		
Fluoxetine (SSRI)	(Anxiety)	No
Sertraline (SSRI)	(Anxiety)	No
	OCD	Yes; ≥6
Fluvoxamine (SSRI)	(Anxiety)	No
	OCD	Yes; ≥10
<b>MDD</b>		
Fluoxetine	MDD	Yes; ≥8
Escitalopram	MDD	Yes; ≥12

ADHD, attention-deficit/hyperactivity disorder; FDA, Food and Drug Administration; MDD, major depressive disorder; NRI, norepinephrine reuptake inhibitor; OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitor.

\*Group 1 medications: evidence of efficacy, favorable side-effect profile, and management of disorder within primary care competencies; for a detailed discussion on pediatric mental health competencies for primary care, see Committee on Psychosocial Aspects of Child and Family Health and Task Force on Mental Health. Policy statement—The future of pediatrics: mental health competencies for pediatric primary care. *Pediatrics*. 2009;124:410–421.

<sup>a</sup>Amphetamine: approved down to age 3 years, “grandfathered” in.

<sup>b</sup>Certain anxiety disorders: generalized anxiety disorder, social anxiety disorder, separation anxiety disorder.

<sup>c</sup>For each of these disorders, there are also evidence-based psychosocial interventions. See *Evidence-Based Child and Adolescent Psychosocial Interventions* at [www.aap.org/mentalhealth](http://www.aap.org/mentalhealth).

The third group of medications includes medications not approved by the FDA for children and thus not included in Groups 1 or 2. For Group 3 medications, there are about 10 that pediatricians are most likely to see in their practices. These 10 medications will be discussed in terms of available efficacy data and adverse-effect profile. Other Group 3 medications, which are not commonly prescribed, will not be discussed, but their adverse-effect profiles can be accessed through electronic media (eg, [drugs@fda.gov](mailto:drugs@fda.gov), Epocrates, Micromedex).

### Evidence Supporting Efficacy

The evidence base for the treatment of ADHD, common anxiety disorders (ie, generalized, social, and separation), and depression has been demonstrated in several multisite randomized clinical trials conducted since the mid-1990s (eg, the MTA Group, Walkup et al, March et al).

The research procedure used to demonstrate efficacy (or not) of a medication is the random assignment, masked (“blinded”), placebo-controlled treatment study (RCT). Additional design features that improve the quality of RCTs include a predetermined primary outcome variable; a sufficiently large number of participants, usually estimated by a power analysis, to accurately test the efficacy hypothesis; multiple performance sites that use comparable methodology; to minimize bias, independent funding (eg, in the United States, the National Institutes of Health (NIH) or another government agency); and use of independent evaluators who do not receive any information about medication side effects.

There is no single gold standard for determining that a medication is efficacious. In adults, 2 well-designed

and conducted RCTs that demonstrate superiority of the active medication over placebo is the generally accepted standard and is used by the FDA as a necessary prerequisite for drug approval. In children and adolescents, because there are fewer funding resources and fewer studies, the FDA sometimes relaxes this standard and approves a medication with just 1 large, high-quality, multicenter RCT along with other supportive data. That approach is also used by the GRADE (Grading of Recommendations Assessment, Development and Evaluation) Working Group to evaluate treatments for children and adolescents ([www.gradeworkinggroup.org](http://www.gradeworkinggroup.org)).

One of the widely recognized limitations with this approach to determining efficacy is that, for both ethical and practical reasons, RCTs are short term, although most psychotropic medications are used to treat children and adolescents with chronic disorders that often require long-term treatment. Despite this limitation, the well-designed and conducted RCT is the best method available for demonstrating efficacy.

As noted earlier, the fact that there are no medications with FDA-approved pediatric indications for an anxiety disorder (except for OCD, an anxiety-related condition) is in large part because of a discrepancy between FDA rules regarding anxiety disorder indications and the efficacy studies that have been conducted in children and adolescents with anxiety. The FDA requires that studies used to support an application for an indication focus on a single anxiety disorder, such as social anxiety disorder (SoAD), separation anxiety disorder (SAD), or generalized anxiety disorder (GAD). In children, symptoms of these anxiety disorders often co-occur and change over time. Thus,

several well-designed studies sponsored by the NIH have examined use of an SSRI, such as fluoxetine, fluvoxamine, or sertraline, to treat children with 1, 2, or 3 of these common childhood anxiety disorders (SoAD, SAD, or GAD). Most commonly, the participants in these

studies met criteria for 2 or 3 disorders, not just 1. Therefore, the FDA did not use data from these studies to support an indication.

Table 62-2 summarizes the efficacy data supporting the use of the Group 1 medications. As a proxy for the

A, active drug recipients; ADHD, attention-deficit/hyperactivity disorder; IE, independent evaluator; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; P, placebo recipients.

<sup>a</sup>Complete references can be found in the electronic version of this chapter (pediatriccare.solutions.aap.org).

<sup>b</sup>Use of independent evaluators to rate symptom severity may help reduce bias because these individuals are blinded to patient side effects that could reveal their treatment assignment.

<sup>c</sup>Standard formulation.

<sup>d</sup>Extended-release formulation.

magnitude of effect, the rate of responders on active drug and placebo are listed. It is important to note that a responder is not the same as a remitter. A patient who remits no longer meets diagnostic criteria and has no or very mild residual symptoms, whereas a responder generally meets a severity criterion of “much better” or “very much better” but may still have mild to moderate symptoms. Thus, a remitter is generally more improved than a responder. The last column notes whether ratings were done by independent evaluators (IEs). An IE is a rater who is not involved in data collection other than to conduct blinded symptom severity ratings at specified times during a study. The use of IEs is thought to reduce bias because the presence or absence of medication side effects (which are not known to the IEs) can help investigators to guess the participant’s medication status—active or placebo. Finally, all completed NIH-sponsored studies are included in the tables. However, there may be unpublished industry-sponsored studies that are not listed.

### Evidence Supporting Safety

There is no gold standard for assessing safety of medications in children and adolescents. For the purposes of this discussion, 5 parameters will be used for assessing safety.

1. An FDA-approved pediatric indication (a proxy for a minimal standard of research data supporting short-term safety [and efficacy] of a medication for a specified indication)
2. At least 10 years on the market (a proxy for sufficient time to discover rare adverse long-term consequences and rare complications with long-term exposure [ie, greater exposure over time increases the chance to detect rare and harmful events that would not otherwise be detected in brief clinical trials])
3. Minimal overdose harm, determined by a review of the available literature
4. Lack of clinically significant boxed warnings (a formal FDA proxy for rare, major adverse events)
5. Lack of other known or potentially harmful long-term effects, determined by a review of available literature and review of “warnings and precautions” in the FDA package inserts

Table 62-3 applies these safety parameters to the 4 categories of Group 1 medications.

## GROUP 1 MEDICATIONS: SPECIFIC RATIONALE

The Group 1 medications for use in the primary care setting belong to 4 different classes of medications. The rationale for using specific medications is presented here.

### Stimulants

Despite the numerous products available on the market, there are just 2 distinct stimulant chemical entities—methylphenidate and amphetamine. The available literature has not shown advantages of different racemic mixtures (*d* vs *l* vs *d,l*). Thus, different racemic preparations are considered interchangeable, except for dose. Methylphenidate and amphetamine are available in numerous release preparations that provide a treatment effect ranging from 3 to 12 hours. Those with longer time on the market and lower cost may be preferred, but that is a general comment, not a preparation-specific recommendation.

### $\alpha_2$ -Adrenergic Agonists

Guanfacine is approved by the FDA for ADHD in children and adolescents. It is relatively specific to the  $\alpha_{2A}$  receptor subtype, which mediates attention and other executive functions. Clonidine is approved by the FDA for ADHD in children and adolescents. It nonspecifically interacts with  $\alpha_{2A}$ ,  $\alpha_{2B}$ , and  $\alpha_{2C}$  receptor subtypes. The B and C receptors mediate the sedation and hypotension or bradycardia side effects. Thus, clonidine may have a less favorable side-effect profile than guanfacine. There are no direct comparative data regarding this issue. Also, regular (not sustained-release) clonidine is associated with acute drops in blood pressure, syncope, and even death following accidental or intentional ingestions of more than therapeutic quantities.

### Norepinephrine Reuptake Inhibitor

Atomoxetine, a norepinephrine reuptake inhibitor, has an FDA indication for ADHD. Of note, it has more

**Table 62-3** Safety Profile of Group 1 Medication Classes in Children and Adolescents

SAFETY CRITERIA	STIMULANTS	$\alpha$ -ADRENERGIC AGENTS	SSRIs	NRIs
FDA approval	$\geq 6$ yr	$\geq 6$ yr	$\geq 8$ yr	$\geq 6$ yr
Years on market <sup>a</sup>	>50 yr	>30 yr	>25 yr	$\geq 10$ yr
Overdose harm	Low	Low	Very low	Very low
Boxed warning (Major AEs) <sup>b</sup>	Drug abuse potential, cardiac	None	Suicidality	Suicidality
Long-term risk to health <sup>c,d</sup>	Possible growth deceleration	None known	None known	None known

AEs, adverse events; FDA, US Food and Drug Administration; NRIs, norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

<sup>a</sup>Years on the market: measure of exposure in large populations; time to observe potentially harmful events.

<sup>b</sup>SSRIs, NRIs, and suicidality: original FDA meta-analysis: 2% for placebo and 4% active in forced dose titration studies (see Hammad TA, Laughren T, Racoosin J. Suicidality in pediatric patients treated with antidepressant drugs. *Arch Gen Psychiatry*. 2006;63(3):332–339). More recent analysis shows difference of 0.67%, down from 2% difference (see Bridge JA et al. Clinical response and risk for reported suicidal ideation and suicide attempts in pediatric antidepressant treatment: a meta-analysis of randomized controlled trials. *JAMA*. 2007;297(15):1683–1696).

<sup>c</sup>Lack of studies to assess long-term risk to health, with the exception of stimulants.

<sup>d</sup>Stimulants and growth deceleration: data are not convincing.

concerning FDA “warnings and precautions” than the other medications for ADHD included in Group 1.

### Selective Serotonin Reuptake Inhibitors

There are 6 SSRIs marketed in the United States: fluoxetine, sertraline, escitalopram, paroxetine, citalopram, and fluvoxamine. Comments regarding the 4 SSRIs included in Group 1 follow:

- Fluoxetine: FDA indications in children and adolescents for depression and OCD; high-quality, NIH-sponsored study demonstrating efficacy for the 3 common anxiety disorders in children; the first SSRI marketed in the United States; longest half-life, so abrupt discontinuation results in slow, safe fall in plasma and brain levels.
- Sertraline: FDA indication in children and adolescents for OCD; second SSRI in the United States; best data for the 3 common anxiety disorders in children; offers alternative to fluoxetine when shorter half-life may be indicated (eg, for a child taking multiple medications with further changes likely) or when fluoxetine cannot be used because of interactions with metabolic isoenzymes (eg, inhibition of CYP2D6).
- Escitalopram: FDA indication in children and adolescents for depression; no clinically relevant interactions with hepatic CYP450 isoenzymes.
- Fluvoxamine: Has an FDA indication for OCD in children and a high-quality, NIH-sponsored study demonstrating efficacy for the 3 common anxiety disorders in children.

## PRESCRIBING GROUP 1 MEDICATIONS IN PEDIATRIC PRIMARY CARE

The general rationale regarding efficacy and safety of psychotropic medications, especially those in Group 1, was described in previous sections. Provided here is a brief introduction to clinical issues associated with prescribing and monitoring of Group 1 psychotropic medications in primary care pediatrics.

### Informed Consent

Obtaining informed consent from the parent or guardian and assent from the patient can be more complicated and difficult for psychotropic medications than for other medications. This is because of parental concerns about the potential effect of medications on the child’s developing brain and controversy in the media regarding psychiatric medications. The basic steps involved in obtaining informed consent and assent are the same, no matter what psychotropic medication is recommended. A description of essential and optional areas to cover in the consent process is provided in Box 62-3. It may be efficient to have a nurse help the prescribing physician with the details of consent, as is commonly done for immunizations and other prescriptions and procedures in outpatient practices. Of note, in addition to the initial consent process, informed consent is usually an ongoing process that unfolds over time as the patient and caregiver develop new questions and concerns about

medications. The initial consent process offers an ideal opportunity to consider a timeline for re-evaluating both medication efficacy and side effects and to note that consent will be revisited in light of the patient’s initial and ongoing responses to and experiences with the medication, both positive and negative. Thus, consent is an ongoing component of an evolving clinical process.

### Dosing

Dosing for all Group 1 medications generally follows the same pattern—start with a relatively low dose, increase in relatively small increments about every week, and continue to increase the dose until an optimal benefit-to-risk ratio is reached. The dosing guidance presented in this chapter for all Group 1 medications is derived from the FDA package inserts, with the authors adding detail on points where the FDA is silent, such as how often or by how much to increase the dose. Dosing recommendations from the FDA can be found in package inserts or at the [drugs@FDA Web site \(www.accessdata.fda.gov/scripts/cder/drugsatfda\)](http://www.accessdata.fda.gov/scripts/cder/drugsatfda).

- Methylphenidate preparations (see Table 62-4): For standard-release preparations, starting doses range from 2.5 mg/dose for preschoolers (ages 4 to 5 years), to 5 mg/dose for school-aged children, to 10 mg/dose for adolescents. Recommended doses for Focalin preparations are half of those for other methylphenidate preparations. Dose increments for increases are generally equivalent to the starting dose. Because response to stimulants may be idiosyncratic, individualized dose titration with interval reports from multiple independent observers is indicated. Optimal benefit-to-risk ratio is common at total daily dose of 0.5 to 1.5 mg/kg per day, although some children respond to lower doses and some adolescents may require higher doses. Some adverse events, such as decreased appetite and insomnia, may be dose sensitive, so higher total daily doses need to be carefully monitored. Most children and families prefer long-acting preparations, which can usually be given once per day. The smallest daily dose of the most popular extended-release methylphenidate preparation (osmotic pump) is 18 mg/day; lower dose increments are available with other formulations.
- Amphetamine preparations (see Table 62-4): 1 mg of amphetamine is approximately equivalent to 2 mg of methylphenidate. Thus, the dosages given previously for methylphenidate can be used for amphetamine preparations, but need to be divided by 2. Long-acting preparations of amphetamine are available in a wide range of doses.
- Guanfacine: For once-daily preparations, which are preferred by children and families, the starting dose is usually 1 mg/day. Doses can be increased by 1 mg every few days to a maximum recommended daily dose of 4 mg.
- Clonidine: 0.1 mg of clonidine is approximately equivalent to 1 mg of guanfacine. Thus, the dosages given previously for guanfacine can be used for clonidine preparations, but need to be divided by 10. Long-acting preparations of clonidine are available in 0.1- and 0.2-mg doses.

**BOX 62-3 A Clinical Approach to Informed Consent for Medication****ESSENTIAL**• **Preamble**

- Conceptualization of signs and symptoms as *illness*
- What are the *risks of not treating* with medication?
- Think *job performance* (home, school, friends)
- Think *development* (emotional, behavioral, social, cognitive)

• **Evidence supporting short-term efficacy and effectiveness**

- A level: 2 placebo-controlled, random-assignment, properly implemented studies (RCTs) or, in some cases for children and adolescents, 1 well-designed RCT
  - *Note:* This applies to all Group 1 medications for attention-deficit/hyperactivity disorder, anxiety, depression.
- B level: 1 RCT
- C level: information from open-label studies, case reports, etc

• **Alternative and additional treatments**

- Evidence-based psychotherapies
- Community, family, school system support
- Other medications

• **Adverse effects**

Severity	Change Needed	Examples
Mild	Requires no change	Dry mouth, transient nausea
Moderate	Requires dose change	Sedation
Severe	Requires stopping drug	Real suicidal ideation or attempt

• **Potential long-term adverse effects**

- Examples: growth restriction (stimulants), diabetes mellitus, or tardive dyskinesia (antipsychotics)
- Unknown

• **Pharmacokinetic issues**

- Convenience: once-daily dosing preferred, no laboratory monitoring preferred
- Drug-drug interactions: especially involving hepatic cytochrome P-450 enzymes

• **Adherence**

- The importance of establishing a convenient daily routine for taking the medication

• **YOUR OPINION ABOUT BENEFIT/RISK RATIO FOR THIS PATIENT**

- Taking into consideration all of the above, what do you recommend?
- Why?
- *Think: if this were your child, what would you do?*

**OPTIONAL**• **Cost**

- Generic vs brand
- This drug vs others in class

• **Evidence supporting long-term efficacy and effectiveness**

- This becomes relevant if/when short-term efficacy and safety are established.

- **Atomoxetine:** Atomoxetine is dosed once daily. For children and adolescents up to 70 kg, the the FDA-recommended initial daily dose is 0.5 mg/kg; target daily dose is 1.2 mg/kg and maximum daily dose is 1.2 mg/kg. For those over 70 kg, initial daily dose is 40 mg; target daily dose is 80 mg, and maximum daily dose is 100 mg. Dosage should be adjusted (lowered) for patients known to be CYP2D6 poor metabolizers.
- **Fluoxetine:** Fluoxetine is dosed once daily. Starting dose ranges from 2.5 to 10 mg, depending on age and weight. Doses are generally increased every week or so by an amount equivalent to the starting dose until a favorable benefit-to-risk ratio is achieved.

Best effective dose is generally 5 to 20 mg, although higher doses are sometimes required.

- **Sertraline:** Sertraline is dosed once daily. Starting dose ranges from 12.5 to 25 mg. Dose increments range from 12.5 to 50 mg. Effective total daily dose is generally 25 to 200 mg.
- **Escitalopram:** Escitalopram is dosed once daily. Starting dose ranges from 2.5 to 5 mg. Dose increments range from 2.5 to 10 mg. Effective total daily dose is generally 5 to 20 mg.
- **Fluvoxamine:** The starting dose is 25 mg at bedtime, with increases of 25 mg every 4 to 7 days as tolerated to maximum effect, not to exceed 200 mg/day (8 to 11 years) or 300 mg/day (12 to 17 years). Daily doses

**Table 62-4** Stimulant Preparations

PREPARATION	DURATION (HR)	METHYLPHENIDATE	AMPHETAMINE
Standard release	3–6	Ritalin Dexmethylphenidate	Dexedrine Adderall
Pulse	7–8	Ritalin SR Metadate ER Methylin ER	Dexedrine Spansule
Pearls	8–12	Metadate CD Ritalin LA FOCALIN XR <sup>a</sup>	Adderall XR
Pump	≤12	Concerta	
Modified standard release (prodrug)	≤12		VYVANSE <sup>b</sup>
Liquid suspension	8–12	QUILLIVANT XR <sup>a</sup>	ProCentra
Patch	≤12	Daytrana <sup>a</sup>	

<sup>a</sup>CAPS indicate that only branded form is available (ie, no generic).

<sup>b</sup>Vyvanse is converted to standard-release dextroamphetamine after the “prodrug” passes through the gut without being metabolized. Thus, it is a “modified” standard-release preparation.

From FDA Listing of Authorized Generics (updated 09/30/2015) ([www.fda.gov/downloads/AboutFDA/CentersOffices/OfficeofMedicalProductsandTobacco/CDER/UCM183605.pdf](http://www.fda.gov/downloads/AboutFDA/CentersOffices/OfficeofMedicalProductsandTobacco/CDER/UCM183605.pdf))

over 50 mg should be divided. Although an extended-release preparation is available, the FDA package insert states that for “pediatric patients naïve to fluvoxamine maleate—the lowest available dose of Luvox CR capsules may not be appropriate.”

### Side Effects or Adverse Events

Adverse events can be evaluated based on either severity or frequency. In package inserts required by the FDA, potential severity of adverse events is emphasized; that is, “boxed warnings” are more severe than “warnings and precautions” (W&P), which are more severe than “adverse reactions.” In addition, package inserts describe “contraindications” and “drug interactions.”

The most comprehensive and least potentially biased prescribing information about adverse events can be found in FDA-required labels or package inserts. These labels are available in various formats and locations, including in medication packaging and the *Physicians’ Desk Reference*. They are available online at [drugs@fda](http://drugs@fda). Since the FDA modified the format for labels a few years ago, each label or insert has a 1-page “Highlights of Prescribing Information” that includes relatively complete and essential information about boxed warnings, warnings and precautions, adverse reactions, contraindications, and drug interactions. These highlights can be accessed and reviewed quickly and conveniently and are useful resources.

Rather than reiterate all the details regarding all the adverse events associated with all of the medications in Group 1, the following 3 sections provide general guidance regarding boxed warnings, warnings and precautions, and adverse reactions. Because contraindications are essentially prohibitions to prescribing, they are not amenable to summarization and should be specifically and carefully considered before prescribing any medication. Likewise, drug interactions, although not prohibitive, are drug specific and generally not amenable to summarization; they should be carefully considered before prescribing any medication.

### FDA Boxed Warnings

The most concerning adverse events are given boxed warnings by the FDA. There is 1 boxed warning for antidepressants (specifically SSRIs and atomoxetine), 1 for stimulants, and none for  $\alpha_2$ -adrenergic agonists. It is important to keep in mind that all the adverse events described in the boxed warnings listed here occur infrequently and may never be seen by an individual pediatrician. The information in the following sections was taken from the most recent labels available at [drugs@fda](mailto:drugs@fda) as of December 9, 2014.

### Selective Serotonin Reuptake Inhibitors (and Atomoxetine) and Suicidality

The FDA boxed warning about suicidality is an obstacle for many pediatricians who consider prescribing SSRIs or atomoxetine for anxiety and depression. The boxed warning issued in October 2004 stated that all antidepressants pose significant risk for suicidality (suicidal ideation or suicide attempts, not completed suicides) in children and adolescents and recommends close monitoring for increased suicidality. Specific recommendations for frequent monitoring were described in an FDA medication guide, which was revised in 2007 ([www.fda.gov/downloads/Drugs/DrugSafety/InformationbyDrugClass/ucm100211.pdf](http://www.fda.gov/downloads/Drugs/DrugSafety/InformationbyDrugClass/ucm100211.pdf)). This updated guide focuses on information parents need to know regarding suicidality and antidepressants rather than on specific mandates for monitoring frequency.

Antidepressant-induced suicidality is rare. The original FDA estimate, based solely on data from more than 4,300 research participants in 23 studies, was that 2% of children and adolescents receiving placebo and 4% receiving an antidepressant developed suicidal thoughts or attempted suicide. Thus, the risk difference was 2%. A subsequent analysis based on data from 27 RCTs involving more than 5,300 participants found a risk difference of just 0.7% (95% confidence interval [CI]: 0.1% to 1.3%). Of note, the most recent estimate, which was based on data from 35 RCTs involving more than 6,000 participants, found a risk

difference of 0.9% (95% CI: 20.000 to 0.018), just reaching statistical significance.

Clinical prudence indicates the need to educate patients and parents about suicidality and to provide careful monitoring for suicidality and other adverse effects during the initial phase of treatment (when the risk for suicidality is generally greatest from both the depression and the medication) and throughout treatment.

### **Stimulants and Concerns About Abuse and Dependence**

The boxed warnings for both amphetamines and methylphenidate state that they have a high potential for abuse and that prolonged administration may lead to dependence. Fortunately, there are no reports of children who were treated with therapeutic doses of stimulants developing dependence. Available data suggest that children with ADHD who are treated with stimulants are not more likely than those who did not receive stimulant treatment to develop substance abuse later in life. A related problem is diversion; that is, patients selling their prescription stimulants to be used as drugs of abuse.

## **FDA Warnings and Precautions**

### **Stimulants**

Most W&Ps rarely occur in children and adolescents treated with stimulants. Those most relevant to children taking either methylphenidate or amphetamine preparations include the following:

- Serious cardiovascular events (generally only in patients with known structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, coronary artery disease, or other serious heart problems)
- Increase in blood pressure (this is more common than other W&Ps)
- Psychiatric adverse events (primarily emergence of psychotic, manic, or aggressive symptoms)
- Seizures
- Long-term growth suppression
- Exacerbation of tics

Priapism is listed only for methylphenidate preparations.

### **$\alpha$ -Adrenergic Agonists**

- Both guanfacine and clonidine preparations have the following relevant W&Ps: hypotension, bradycardia, syncope
- Sedation and somnolence
- Worsening of some pre-existing cardiac conduction abnormalities

In addition, abrupt discontinuation should be avoided with clonidine preparations.

### **Atomoxetine**

Atomoxetine has the following relevant W&Ps:

- Severe liver injury
- Serious cardiovascular events
- Effects on blood pressure and heart rate
- Emergent psychotic or manic symptoms
- Bipolar disorder
- Aggressive behavior or hostility

- Possible allergic reactions (in addition to the standard contraindication for hypersensitivity)
- Effects on urine outflow
- Priapism
- Growth
- Concomitant use with potent CYP2D6 inhibitors.

### **Selective Serotonin Reuptake Inhibitors**

The SSRIs fluoxetine, sertraline, escitalopram, and fluvoxamine all have the following relevant W&Ps, all of which rarely occur:

- Serotonin syndrome
- Activation of mania/hypomania
- Seizures
- Abnormal bleeding
- Hyponatremia
- Potential cognitive and motor impairment
- Angle closure glaucoma

Fluoxetine has some additional relevant W&Ps—altered appetite and weight, anxiety and insomnia, QT prolongation, long half-life (thus, changes in dose may not be reflected in plasma for several weeks).

Sertraline, escitalopram, and fluvoxamine all have a W&P regarding discontinuation of treatment, specifically concerns about various withdrawal symptoms with abrupt discontinuation.

Fluvoxamine has a W&P regarding potentially important drug interactions, beyond those described in the “drug interactions” section of the label. These are generally related to inhibiting effect of fluvoxamine on several cytochrome P-450 isoenzymes, including 1A2, 2C9, 3A4, and 2C19.

### **Adverse Reactions**

The FDA label uses frequency, rather than severity, to delineate adverse reactions, the most common and least severe of adverse events. Although specifics vary from medication to medication, the label usually describes the most common adverse reactions (>5% and at least twice the placebo rate) reported in RCTs submitted to the FDA. This report may be for adults, children, adolescents, or some combination of these groups.

In Table 62-5, common and less common adverse events for the 4 classes of Group 1 medications are presented. Table 62-5 is based on, but not completely the same as, adverse reactions presented in FDA-approved labels. In addition, withdrawal symptoms are noted. Except for low-dose stimulants and fluoxetine, medications should be tapered in order to minimize withdrawal symptoms.

### **Monitoring Group 1 Medications**

Frequency of monitoring may vary depending on a particular patient's health status, but, in general, it is more frequent during the initial phase of treatment with all Group 1 medications. During this time, dosage is changing frequently as it is being titrated up to an effective and safe dose, and side effects often occur before benefit. Poor adherence is common, so monitoring for adherence is important to prevent unwarranted and potentially unsafe dose escalations in the child who is not adherent. Pediatricians will benefit from access to pharmacy claims data or other medication adherence tools, if available. Finally, more

**Table 62-5** Adverse Reactions Associated With Group 1 Medication Classes

MEDICATION CLASS	ADVERSE REACTIONS <sup>a</sup>	WITHDRAWAL SYMPTOMS <sup>b</sup>
<b>STIMULANTS</b> Methylphenidate (Ritalin and others) Dexmethylphenidate (Focalin) Dextroamphetamine (Dexedrine and others) Amphetamine salts (Adderall and others)	<i>Common: insomnia, appetite suppression, headache, stomachache</i> Less common: cognitive dulling, irritability, exacerbation of tics <b>MONITOR:</b> BP, pulse, BMI	ADHD symptoms “worsen” at end of day when drug wears off. These are not considered withdrawal symptoms.
<b>α<sub>2</sub>-ADRENERGIC AGONISTS</b> Guanfacine (Tenex, Intuniv) Clonidine (Catapres, Kapvay)	<i>Common: somnolence</i> Less common: dry mouth, headache, nausea, decreased BP <b>MONITOR:</b> BP, pulse	Elevated BP, nervousness, headache, confusion
<b>NRIs</b> Atomoxetine (Strattera)	<i>Common: dry mouth, insomnia, nausea, decreased appetite</i> Less common: increased heart rate, BP, palpitations, dizziness, sweating, dysuria, weight change <b>MONITOR:</b> BMI, BP, HR	
<b>SSRIs</b> Fluoxetine (Prozac) Sertraline (Zoloft) Escitalopram (Lexapro) Fluvoxamine (Luvox)	<i>Common: “activation” (restlessness, insomnia, impulsiveness, talkativeness—usually occur early in treatment), GI upset, nausea, diarrhea</i> Less common: autonomic (eg, diaphoresis, mydriasis), cardiovascular (eg, flushing, sinus tachycardia, hypertension), sexual (decreased libido, delayed ejaculation), akathisia <b>MONITOR:</b> BMI, worsening of depression, emergence of suicidal thinking or behavior (especially with initiation or dose escalation), or unusual changes in behavior, such as sleeplessness, agitation, or withdrawal from normal social situations	Especially for shorter half-life SSRIs such as sertraline: flu-like syndrome; dizziness (most common), nausea, emesis, fatigue, headache, gait instability, insomnia, mood changes, myalgia. Tapering not needed for fluoxetine.

ADHD, attention-deficit/hyperactivity disorder; BP, blood pressure; BMI, body mass index; HR, heart rate; NRI, norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

<sup>a</sup>Common adverse reactions in italics.

<sup>b</sup>Tapering suggested for all medications except fluoxetine.

Check for psychopharmacologic medication updates from a reliable source, such as the National Library of Medicine or National Institutes of Health, MedlinePlus Drugs, Supplements and Herbal Information. Available at: <http://www.nlm.nih.gov/medlineplus/druginformation.html>; US Food and Drug Administration. Available at: <http://www.fda.gov>; American Academy of Child and Adolescent Psychiatry. Available at: <http://www.aacap.org>. Practice Parameter on the Use of Psychotropic Medication in Children and Adolescents: The AACAP Practice Parameters describe generally accepted practices. They are designed to assist physicians in providing high-quality assessment and treatment for children and adolescents consistent with best available scientific evidence and clinical consensus. Available at: <http://download.journals.elsevierhealth.com/pdfs/journals/0890-8567/PIIS0890856709601568.pdf>.

frequent monitoring may be indicated for patients with certain medical conditions.

For stimulants, blood pressure, heart rate, height, and weight should be monitored. In addition, patients taking stimulants should be observed for, and parents questioned about, tics. No specific laboratory studies are recommended. The recommendations for guanfacine, clonidine, and atomoxetine are similar.

Patients taking SSRIs should be monitored for several parameters during the first several weeks of treatment: emergence of suicidal thinking or behavior, worsening of depression, gastrointestinal symptoms (pain, nausea, diarrhea), or the activation phenomenon (eg, agitation, insomnia, or increased energy or activity). Over the longer term, height and weight, sexual

dysfunction, and emergence of mania should be monitored. No specific laboratory tests are indicated.

### Phases of Treatment

Medication treatment for ADHD, anxiety, or depression is often initiated during an acute clinical crisis when the child's symptoms are at their worst. Thus, doses that are used in the acute phase of illness and treatment may be higher than are needed later during maintenance treatment. This is especially true if the child and family are responsive to evidence-based psychosocial therapy that is initiated during the acute clinical crisis or shortly thereafter. Improved coping skills, more useful cognitive and behavioral constructs, reduced family tension, or successful behavioral

feedback may reduce the need for medication either partially (eg, lower dose) or completely (eg, discontinuation). Over the longer term, doses may need to be increased in response to growth and maturation.

### Adherence and Persistence

Obviously, medications that are not ingested are not effective. The rate of nonadherence in pediatric psychopharmacology is not well studied or documented except for stimulants, for which the data suggest high levels of nonadherence. Parent reports of adherence to sustained-release stimulant preparations indicate about 10% to 25% nonadherence. Even more concerning, a retrospective comparison of the Multimodal Treatment Study of Attention-Deficit/Hyperactivity Disorder (MTA) found that only 3% of caregivers reported that their child did not receive prescribed stimulant medication on the day of a study visit, whereas child saliva samples indicated that 25% of children were nonadherent. Taken together, studies of parent reports and salivary samples indicate that nonadherence to stimulant medication is high and is underreported by caregivers.

Persistence refers to continuity of treatment. Because ADHD is a chronic disorder, relatively long-term treatment with stimulants would be expected except for drug holidays or when they are discontinued because of unacceptable side effects or lack of adequate effect. However, data from community practice settings suggest that treatment is not persistent. In a study of more than 9,500 pharmacy and medical claims for 6- to 12-year-olds, the mean duration of stimulant treatment episodes was only about 145 days for immediate-release preparations and about 150 to 160 days for longer-acting preparations. In a study using Medicaid claims for more than 40,000 5- to 20-year-olds, 27% to 50% were persistent for 12 months, allowing for a 1- or 3-month gap in use, respectively. These and other studies suggest that a substantial proportion of children receiving stimulants may not receive them for more than 1 year.

Improving adherence and persistence is not a simple or easy task. Discussing adherence and nonadherence in a nonjudgmental manner before prescribing a medication is important. It is important to establish a therapeutic approach through which children and parents feel that assessing adherence is part of the therapeutic process, helpful to clinical decision making regarding dose changes and continuation of a medication, and not a negative judgment.

Procedures for improving adherence and persistence are described in the literature and in Chapter 47, Adherence to Pediatric Health Care Recommendations. They include identification of barriers to adherence, application of motivational interviewing techniques, reminder and monitoring systems, and, when available, aids such as bubble packaging.

### Prioritizing Medications

The following discussion regarding differences between various Group 1 medications is offered as potentially useful information. It is not meant to protocolize or prohibit prescribing of any medication. An individualized decision regarding an individual medication for

an individual patient is always the final responsibility of the individual prescriber.

### Attention-deficit/Hyperactivity Disorder

Clinical guidance from the AAP and practice parameters from the American Academy of Child and Adolescent Psychiatry (AACAP) recommends starting with either methylphenidate or amphetamine. Also, the effect size, a measure of the magnitude of improvement relative to placebo, is greater for these stimulants than for the other medications approved for ADHD. In cases in which there are concerns about starting with a stimulant (eg, specific potential adverse events or parental preferences), guanfacine, clonidine, and atomoxetine are all secondary options and all have generally comparable effect sizes. As described previously, guanfacine and clonidine seem to have a favorable adverse event profile compared with atomoxetine.

### Anxiety

There are no data to suggest any differences in efficacy between fluoxetine, sertraline, and fluvoxamine for anxiety. Fluoxetine has a longer half-life and effect, which is an advantage if there are concerns about adherence, but a disadvantage if there is a need to stop the medication because of adverse effects or drug interactions. Fluvoxamine inhibits cytochrome P-450 isoenzymes that are different from those inhibited by fluoxetine or sertraline.

### Depression

There are no data to suggest any differences in efficacy for depression between fluoxetine and escitalopram. The potential advantages and disadvantages of fluoxetine for depression are the same as described previously for anxiety. An advantage of escitalopram is that it does not have any clinically significant interactions with cytochrome P-450 isoenzymes.

### Switching Medications

If the initial stimulant medication is not effective, data from published studies supports switching to a stimulant in the other category. Likewise, if the initial SSRI is not effective, switching to one of the other Group 1 SSRIs may be successful.

### Multiple Medications

Many children treated in the pediatric primary care setting for ADHD, anxiety, or depression will need only 1 psychotropic medication. Some will need 2 (eg, children with ADHD, anxiety, and depression who require medication as part of the treatment plan). Fortunately, the medications for ADHD (methylphenidate, amphetamine, guanfacine, clonidine, and atomoxetine) can be used safely in combination with the medications for anxiety or depression (the SSRIs fluoxetine, sertraline, escitalopram, and fluvoxamine).

If a child requires 3 or more psychiatric medications to effectively manage symptoms, advanced expertise in pediatric psychopharmacology or consultation with a child and adolescent psychiatrist is strongly advised. The pediatrician can, in either case, play an important

role in monitoring the medications and in promoting a healthy lifestyle.

## GROUP 2 MEDICATIONS FOR OTHER DISORDERS: GENERAL RATIONALE

In addition to prescribing and monitoring Group 1 medications, pediatricians are ideally suited to collaborate with psychiatrists and other mental health specialists in the care of children with more severe or uncommon disorders. They may be asked to take on partial responsibility for monitoring the therapeutic and side effects of a variety of other medications, which are included in Groups 2 and 3.

Group 2 medications can be monitored in primary care settings, but because they generally have a more serious safety profile or more complicated monitoring requirements than Group 1 medications, they are generally prescribed by specialists—child psychiatrists, developmental-behavioral pediatricians, specialists in neurodevelopmental disabilities or adolescent medicine, pediatric neurologists, or adult psychiatrists with additional training in adolescent psychiatry. Depending on an individual pediatrician's skills and experience and availability of specialists for referral (or lack thereof, especially in rural and underserved areas), some pediatricians with additional training in pediatric psychopharmacology may choose to prescribe Group 2 medications.

Group 2 includes all FDA-approved medications for children with other disorders (ie, not ADHD, anxiety, or depression). Group 2 includes 5 second-generation antipsychotics (SGAs; aripiprazole, olanzapine, quetiapine, risperidone, and paliperidone) and lithium, a mood stabilizer. The SGAs (all 5) are approved for treatment of children with psychosis in schizophrenia; all except paliperidone are approved for mania in bipolar disorder; only risperidone and aripiprazole are approved for “irritability” in autism. However, these medications are most commonly used off label (ie, outside the FDA indications) in children to treat behavioral problems, especially aggression. Lithium is approved by the FDA for treatment of acute mania in bipolar disorder. Lithium is also used off label to treat nonbipolar mood instability.

## GROUP 2 MEDICATIONS: SPECIFICS

### Antipsychotics

Antipsychotic medications can reduce the severity of various major psychiatric symptoms and have a variety of effects, including the following:

- Antipsychotic effects for hallucinations, delusions, and disorganized thinking
- Mood stabilizing effects for mania, irritability, and mood instability
- Possible “organizing” or calming effects for agitation and aggressive behavior

However, of all the psychotropic medications used in children and adolescents, SGAs generally have the most concerning adverse effects, including the following:

- Sedation
- Weight gain
- Elevated glucose and insulin resistance

- Elevated triglycerides and cholesterol
- Abnormal movements (neurologic)
- Others (see Table 62-6)

Many of the major adverse effects of SGAs—particularly weight gain, metabolic abnormalities, and involuntary movements—can develop into major health problems (eg, cardiovascular disease and its consequences, tardive dyskinesia) during long-term treatment and may not be reversible. Most disorders that may be treated with SGAs are chronic and generally require long-term treatment. Thus, determining risk versus benefit when initiating SGAs is difficult.

There is no agreement about monitoring for weight and metabolic adverse events in children prescribed SGAs. Neither the AAP nor the AACAP has issued formal guidelines or recommendations for monitoring. The only available formal published guide is for adults; it is presented in Table 62-7.

The following discussion regarding differences between various Group 2 medications is offered as potentially useful information. It is not meant to protocolize or prohibit prescribing of any medication. An individualized decision regarding an individual medication for an individual patient is always the final responsibility of the individual prescriber.

There are no useful data comparing the efficacy of the 5 Group 2 SGAs in children. Paliperidone is the active metabolite of risperidone and seems similar to risperidone in efficacy and adverse event profile. Perhaps the major difference is that risperidone has been in use longer (since 1993) than paliperidone (since 2006) and is available as a generic drug. Generally, clinically meaningful differences between SGAs focus on adverse events. Only a few relevant differences will be highlighted here. Olanzapine, in contrast to the other Group 2 SGAs, is associated with more weight gain and metabolic adverse events. Aripiprazole is associated with the least weight gain and less severe metabolic adverse events. Among the 4, risperidone is most likely to increase prolactin levels and is associated with gynecomastia and amenorrhea. Quetiapine seems to be the most sedating. Detailed information regarding Group 2 SGAs is presented in Table 62-6.

### Lithium

Mood stabilizers (excluding antipsychotics) are used to treat mania, depression, irritability, and problematic mood swings or instability in bipolar disorder and other mood disorders. There are 2 groups of mood stabilizers—traditional (lithium, valproic acid [divalproex sodium], and carbamazepine) and newer anti-convulsants (eg, lamotrigine). Use of mood stabilizers (excluding SGAs) in children appears to be decreasing. This may result from 1 or more factors—available efficacy data are generally negative, regular monitoring of plasma levels is usually required, and the adverse event burden is substantial.

Lithium is the mood stabilizer included in Group 2. It has an FDA indication for mania in bipolar disorder down to age 12 years, and available data for lithium suggest efficacy for acute mania in bipolar disorder. Detailed information regarding lithium is presented in Table 62-6.

**Table 62-6**      **Group 2 Medications**

MEDICATION	WARNINGS, PRECAUTIONS, AND ADVERSE EVENTS	COMMENTS
<b>SECOND-GENERATION ANTIPSYCHOTICS (SGAS)</b>		
<b>Risperidone</b> Class: SGA <i>Indications in children and adolescents:</i> schizophrenia (13–17 yr), acute manic or mixed episodes (10–17 yr), “irritability” associated with autistic disorder (5–16 yr) <i>Uses:</i> schizophrenia spectrum disorders, bipolar spectrum disorders, “irritability” in autism. Also, among many off-label uses: acute aggression, chronic irritability, tics, and other disorders not responsive to other medications <i>Monitoring:</i> height and weight. Fasting glucose and lipid profile. Abnormal involuntary movements.	<i>Box warnings:</i> suicidality with antidepressant drugs <i>Warnings and precautions:</i> increased risk for suicidality in children, adolescents, and young adults with major depressive disorder, neuroleptic malignant syndrome, tardive dyskinesia, hyperglycemia/diabetes mellitus, dyslipidemia, weight gain, orthostatic hypotension, leukopenia, neutropenia, agranulocytosis, seizures/convulsions, potential for cognitive and motor impairment, suicide <i>Adverse events:</i> In children and adolescents clinical trials (incidence $\geq 5\%$ and twice placebo): somnolence, extrapyramidal disorder, fatigue, nausea, akathisia, blurred vision, salivary hypersecretion, dizziness, tremor, sedation, fatigue, increased appetite, drooling, vomiting, pyrexia, decreased appetite, lethargy	Risperidone was the first SGA (other than clozaril, which is rarely used in children) approved by the US Food and Drug Administration (FDA) in 1993 for marketing in the United States. It is generally effective and safe for short-term use, but there are concerns about adverse effects of long-term use, such as obesity, diabetes, metabolic syndrome, and tardive dyskinesia. It can increase prolactin levels and is associated with gynecomastia and amenorrhea.
<b>Aripiprazole</b> Class: SGA <i>Indications in children and adolescents:</i> schizophrenia (13–17 yr), manic or mixed episodes (10–17 yr), “irritability” associated with autistic disorder (6–17 yr) <i>Uses:</i> same as risperidone <i>Monitoring:</i> same as risperidone	Same as risperidone	Marketed since 2002, aripiprazole has a somewhat different mechanism of action than other SGAs. It is associated with less weight gain than other SGAs, except ziprasidone. It also lowers prolactin levels.
<b>Quetiapine</b> Class: SGA <i>Indications in children and adolescents:</i> schizophrenia (13–17 yr), manic episodes associated with bipolar I disorder (10–17 yr) <i>Uses:</i> same as risperidone <i>Monitoring:</i> same as risperidone	Same as risperidone	Marketed since 1997, quetiapine is associated with more somnolence than other SGAs.
<b>Olanzapine</b> Class: SGA <i>Indications in children and adolescents:</i> schizophrenia (13–17 yr), manic or mixed episodes of bipolar I disorder (13–17 yrs) <i>Uses:</i> same as risperidone <i>Monitoring:</i> same as risperidone	<i>Box warnings:</i> none specifically applicable for pediatrics <i>Warnings and precautions:</i> suicide, neuroleptic malignant syndrome, hyperglycemia, hyperlipidemia, tardive dyskinesia, orthostatic hypotension, leukopenia, neutropenia and agranulocytosis, seizures, potential for cognitive and motor impairment, hyperprolactinemia <i>Adverse events:</i> in adolescent clinical trials ( $\geq 5\%$ and at least twice that for placebo): somnolence, dizziness, fatigue, increased appetite, nausea, vomiting, dry mouth, tachycardia, weight gain	Marketed since 1996, olanzapine is associated with more weight gain and related metabolic side effects in adolescents than other SGAs. <sup>a,b</sup>

MEDICATION	WARNINGS, PRECAUTIONS, AND ADVERSE EVENTS	COMMENTS
<p><b>Paliperidone</b>  Class: SGA  Indications in children and adolescents: schizophrenia (12–17 yr)  Uses: same as risperidone  Monitoring: same as risperidone</p>	<p><i>Box warnings:</i> none specifically applicable for pediatrics  <i>Warnings and precautions:</i> neuroleptic malignant syndrome, QT prolongation, tardive dyskinesia, hyperglycemia and diabetes mellitus, hyperglycemia, dyslipidemia, weight gain, hyperprolactinemia, gastrointestinal narrowing, orthostatic hypotension and syncope, leukopenia, neutropenia, agranulocytosis, potential for cognitive and motor impairment, seizures, suicide  <i>Adverse events:</i> most common adverse reactions in adolescent clinical trials (<math>\geq 5\%</math>) were somnolence, akathisia, tremor, dystonia, cogwheel rigidity, anxiety, weight increased, tachycardia</p>	<p>Because paliperidone is the major active metabolite of risperidone, it is very similar to risperidone in all respects.</p>
<p><b>MOOD STABILIZER</b>  <b>Lithium</b>  Class: element of the alkali metal group (salt)  Indications in children and adolescents: mania in bipolar disorder (age <math>&gt;12</math> yr)  Uses: acute mania and maintenance therapy in bipolar disorder, mood stabilization  Monitoring: pregnancy testing, electrocardiogram, serum lithium levels, complete blood count, electrolytes, thyroid function, renal function</p>	<p><i>Box warnings:</i> toxicity closely related to serum levels; can occur close to therapeutic dose levels.  <i>Warnings:</i> very high risk for toxicity: significant cardiovascular or renal disease, severe debilitation, dehydration, sodium depletion; taking diuretics or angiotensin-converting enzyme (ACE) inhibitors. Chronic use may lower renal concentrating ability, can present as nephrogenic diabetes insipidus, with polyuria/polydipsia. Encephalopathic syndrome (ie, weakness, lethargy, fever, tremulousness and confusion, leukocytosis, extrapyramidal symptoms, elevated serum enzymes, blood urea nitrogen, and fasting blood sugar) may occur with lithium and a neuroleptic, often haloperidol.  <i>Precautions:</i> hypothyroidism; impaired mental or physical abilities; any concomitant medications, ie, diuretics, ACE inhibitors, carbamazepine, fluoxetine.  <i>Adverse events:</i> Mild <math>&lt;1.5</math> mEq/L; mild/moderate 1.5–2.5 mEq/L; moderate/severe <math>\geq 2.0</math> mEq/L. Less than 2.0 mEq/L: early signs of toxicity, including diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination; at higher levels: giddiness, ataxia, blurred vision, tinnitus, large output of dilute urine; at <math>&gt;3.0</math> mEq/L: complex clinically with multiple organs and organ systems.</p>	<p>Introduced in the United States in the early 1960s, it was the original mood stabilizer. Clear, documented evidence of effectiveness for acute and maintenance treatment of mania and bipolar disorder in adults. No well-powered, placebo-controlled study for treatment of mania in children and adolescents, in large part because of the ethical and practical difficulties associated with conducting placebo-controlled studies. Evidence is mixed from several smaller studies.<sup>c,d</sup> Indication for 12- to 17-year-olds is not based on rigorous safety and efficacy data. Unpopular with children and adolescents because of common side effects and the need for repeated venipunctures for serum level monitoring.</p>

### GROUP 3 MEDICATIONS

As noted previously, the third group of medications (Group 3) includes medications not approved by the FDA for children and thus not included in Groups 1 or 2. It should be noted that there are a few other medications that have FDA indications for children, but these are based on premodern data (if there are any data) and were “grandfathered” in by the FDA years ago. Although the FDA has removed most of these grandfathered indications, a few remain. These remaining grandfathered approvals have been excluded from this conceptual framework because they were not subject to the same modern standards of evidence for safety and efficacy as medications included in Groups 1 and 2, discussed previously.

For Group 3 medications, 10 were selected for emphasis because they are commonly used and pediatricians are likely to have patients for whom they have been prescribed. Table 62-8 summarizes available efficacy data and adverse event profiles for these 10 medications. Other Group 3 medications, which are less commonly prescribed, will not be discussed, but their adverse event profiles can be accessed by electronic media (eg, drugs@fda, Epocrates, Micromedex).

#### Other Antidepressants

Four antidepressants—bupropion, citalopram, venlafaxine, and mirtazapine—are commonly prescribed in children and adolescents. None has an FDA indication for use in children or adolescents.

Bupropion has a chemical structure similar to the phenylethylamines, which are stimulants. It is marketed for depression in adults and is sometimes used to treat comorbid depression and ADHD in children.

Although citalopram, an SSRI, is sometimes used for depression or anxiety in children, it offers no

benefit over escitalopram, a Group 1 medication, which is the therapeutically effective s-enantiomer of citalopram. Citalopram has an FDA warning regarding maximum dose in adults because of the risk for QTc prolongation; however, a relevant dosage maximum is not known in children and adolescents. Thus, the need to monitor with electrocardiograms complicates treatment in children.

Venlafaxine is a norepinephrine reuptake inhibitor that acts like an SSRI at lower doses. It is used for anxiety or depression in children. In children and adolescents, venlafaxine is associated with more adverse events than SSRIs. Industry-sponsored efficacy studies for depression and anxiety in children, although almost reaching statistical significance, have not demonstrated clear efficacy.

Mirtazapine has a tetracyclic chemical structure that distinguishes it from other antidepressants. It is marketed for depression in adults. Mirtazapine is associated with more sedation and weight gain than other antidepressants.

#### Other Antipsychotics

Ziprasidone is an SGA (marketed since 2001) that is approved in adults for psychosis in schizophrenia and mania in bipolar disorder. Ziprasidone has the advantage of generally being associated with less weight gain and fewer metabolic adverse events than other SGAs. Probably primarily because ziprasidone is associated with prolongation of QTc, it has not been approved by the FDA for children or adolescents.

#### Other Mood Stabilizers

Divalproex sodium, an anticonvulsant, is commonly prescribed to children as a mood stabilizer. Unfortunately, efficacy data for divalproex sodium suggest no difference from placebo and less efficacy than comparators. Monitoring requires venipunctures.

**Table 62-8**      **Group 3 Medications**

MEDICATION	WARNINGS, PRECAUTIONS, AND ADVERSE EVENTS	COMMENTS
<b>ANTIDEPRESSANTS</b>		
<b>Bupropion</b> Class: atypical antidepressant; chemical structure like phenylethylamines, which are stimulants Indications: <i>adult</i> : major depressive disorder (MDD) C/A: <b>none</b> Uses: depression Monitoring: blood pressure, heart rate, height, weight, suicidality	<i>Boxed warnings:</i> suicidality <i>Warnings and precautions:</i> seizures, hepatotoxicity, agitation and insomnia, psychosis and confusion, weight gain or loss, allergic reactions, hypertension <i>Adverse reactions:</i> agitation, dry mouth, insomnia, headache/migraine, nausea and vomiting, constipation, tremor	Because of its structural similarity to stimulants, bupropion is sometimes used to treat both depression and symptoms of ADHD.
<b>Citalopram</b> Class: selective serotonin reuptake inhibitor (SSRI) Indications: <i>adult</i> : MDD C/A: <b>none</b> Uses: MDD Monitoring: same as other SSRIs (see Group 1)	<i>Boxed warnings:</i> suicidality, electrocardiogram changes <i>Warnings and precautions:</i> similar to other SSRIs <i>Adverse reactions:</i> similar to other SSRIs	Offers no benefit over escitalopram, which is the Group 1 therapeutically effective s-enantiomer of the racemic mixture citalopram. Also, citalopram has a US Food and Drug Administration (FDA) warning regarding maximum dose in adults because of the risk for QTc prolongation; relevant dosage maximum is not known in children and adolescents. Thus, the potential need to monitor with electrocardiograms complicates treatment.
<b>Venlafaxine</b> Class: norepinephrine reuptake inhibitor (NRI) Indications: <i>adult</i> : MDD C/A: <b>none</b> Uses: MDD Monitoring: blood pressure, heart rate, height, weight, suicidality	<i>Boxed warnings:</i> suicidality <i>Warnings and precautions:</i> serotonin syndrome, sustained hypertension, mydriasis, discontinuation symptoms—especially anxiety and insomnia, decreased appetite and weight, height deceleration, activation of mania/hypomania, hyponatremia, seizures, increased risk for bleeding events, serum cholesterol elevation, interstitial lung disease, eosinophilic pneumonia <i>Adverse reactions:</i> asthenia, sweating, nausea, constipation, anorexia, vomiting, somnolence, dry mouth, dizziness, nervousness, anxiety, tremor, blurred vision	Venlafaxine was compared with an SSRI in children and adolescents with depression who had not responded to initial treatment with an SSRI (TORDIA study). The second SSRI and venlafaxine showed comparable efficacy; however, venlafaxine was associated with more adverse events and discontinuations.
<b>Mirtazapine</b> Class: tetracyclic Indications: <i>adult</i> : MDD C/A: <b>none</b> Uses: MDD Monitoring: body mass index, white blood cell lipid panel, transaminases	<i>Boxed warnings:</i> suicidality <i>Warnings:</i> activation of mania/hypomania, agranulocytosis, serotonin syndrome, angle closure glaucoma <i>Precautions:</i> discontinuation symptoms, akathisia, hyponatremia, somnolence, dizziness, increased appetite, weight gain, cholesterol/triglycerides, transaminase elevations, seizures <i>Adverse reactions:</i> somnolence, increased appetite, weight gain, dizziness	Mirtazapine has both serotonergic and noradrenergic actions and is different from other Class 1 and 2 antidepressants in its mechanism of action. It is generally more sedating and causes more weight gain than other antidepressants.

Table 62-8

Group 3 Medications—cont'd

MEDICATION	WARNINGS, PRECAUTIONS, AND ADVERSE EVENTS	COMMENTS
<b>SECOND-GENERATION ANTIPSYCHOTIC (SGA)</b>		
<b>Ziprasidone</b> <i>Class:</i> SGA <i>Indications:</i> adult: schizophrenia, manic or mixed episodes associated with bipolar I disorder, adjunctive maintenance therapy of bipolar I disorder, agitation in schizophrenic patients (intramuscular injection) <i>C/A:</i> none <i>Uses:</i> same as risperidone <i>Monitoring:</i> same as risperidone, plus QTc prolongation on electrocardiogram	<i>Boxed warnings:</i> not applicable for pediatrics <i>Warnings and precautions:</i> QT interval prolongation, neuroleptic malignant syndrome, tardive dyskinesia, hyperglycemia and diabetes mellitus, dyslipidemia, rash, orthostatic hypotension, leukopenia, neutropenia, agranulocytosis, seizures, potential for cognitive and motor impairment, suicide <i>Adverse events:</i> most common adverse reactions in clinical trials (incidence $\geq 5\%$ and twice placebo): somnolence, respiratory tract infection, somnolence, extrapyramidal symptoms, dizziness, akathisia, abnormal vision, asthenia, vomiting, extrapyramidal symptoms, dizziness, akathisia, abnormal vision, asthenia, vomiting, headache, nausea	Marketed since 2001, ziprasidone is associated with less weight gain than other SGAs. Because of potential to prolong the QT interval, electrocardiogram monitoring is needed.
<b>MOOD STABILIZER</b>		
<b>Valproic Acid</b> <i>Class:</i> anticonvulsant mood stabilizer <i>Indications:</i> adult: therapy of complex partial seizures and simple and complex absence seizures <i>C/A:</i> none for psychiatric disorders <i>Uses:</i> mood stabilizer <i>Monitoring:</i> pregnancy testing, serum levels, complete blood count, liver function tests	<i>Boxed warnings:</i> hepatotoxicity can be fatal, usually in first 6 months of use in children $< 2$ years; teratogenic, includes neural tube defects, eg, spina bifida, malformations, decreased IQ; pancreatitis can be fatal, hemorrhagic cases <i>Warnings and precautions:</i> hepatotoxicity, birth defects and decreased IQ following in utero exposure, pancreatitis, suicidality, thrombocytopenia, multiorgan hypersensitivity reaction, hypothermia, hyperammonemia, hyperammonemic encephalopathy, multiorgan hypersensitivity reaction <i>Adverse reactions:</i> most common adverse reactions in clinical trials of mania (incidence $\geq 5\%$ ): abdominal pain, alopecia, amblyopia/blurred vision, amnesia, anorexia, asthenia, ataxia, bronchitis, constipation, depression, diarrhea, diplopia, dizziness, dyspepsia, dyspnea, ecchymosis, emotional lability, fever, flu syndrome, headache, increased appetite, infection, insomnia, nausea, nervousness, nystagmus, peripheral edema, pharyngitis, rhinitis, somnolence, abnormal thinking, thrombocytopenia, tinnitus, tremor, vomiting, weight gain, weight loss	Valproic acid to treat mania in adults is supported by substantial data. Supportive data are lacking in children. An industry-funded, multisite randomized controlled trial in children with mania and bipolar disorder did not show efficacy of valproic acid versus placebo. In a comparison of valproic acid, lithium, and risperidone for bipolar disorder in children, valproic acid had the lowest response rates, which were comparable to those for placebo in the industry-funded study.

**Table 62-8**      **Group 3 Medications—cont'd**

MEDICATION	WARNINGS, PRECAUTIONS, AND ADVERSE EVENTS	COMMENTS
<b>ANXIOLYTICS</b> <b>Lorazepam</b> Class: benzodiazepine Indications: adult: acute anxiety C/A: none Uses: acute anxiety Monitoring: pregnancy testing	Boxed warnings: none Warnings: worsening or emergence of depression, suicidality, respiratory depression, interference with cognitive and motor performance, physical and psychological dependence, risk of use in pregnancy, withdrawal symptoms Precautions: paradoxical reactions (ie, behavioral disinhibition), should not be used with alcohol Adverse reactions: in a sample of about 3,500 adult patients treated for anxiety, the most frequent adverse reaction was sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%), and unsteadiness (3.4%)	Lorazepam is a short-acting benzodiazepine with a duration of effect of about 4 to 8 hours. Primarily because of the possibility of physical and psychological dependence with prolonged use of benzodiazepines, lorazepam is generally recommended only for short-term use (days to a few weeks) for treatment of acute and severe anxiety following a trauma or preceding a medical procedure or while waiting for an SSRI or other anxiolytic to become effective.
<b>Clonazepam</b> Class: benzodiazepine Indications: adult: panic disorder C/A: none Uses: acute anxiety Monitoring: pregnancy testing	Boxed warnings: none Warnings: interference with cognitive and motor performance, suicidality, physical and psychological dependence, risk of use in pregnancy, withdrawal symptoms Precautions: worsening of seizures, hypersalivation, should not be used with alcohol Adverse reactions: somnolence, abnormal coordination, ataxia, depression	Clonazepam is similar to lorazepam, except for its longer half-life and once-daily dosing.
<b>SLEEP AIDS</b> <b>Trazodone</b> Class: serotonergic potentiator with unclear specific mechanism of action. Indications: adult: MDD C/A: none Uses: insomnia Monitoring: pregnancy testing	Boxed warnings: suicidality Warnings and precautions: serotonin syndrome, angle closure glaucoma, activation of mania/hypomania, QT prolongation, orthostatic hypotension and syncope, abnormal bleeding, interaction with monoamine oxidase inhibitors, priapism, hyponatremia, potential for cognitive and motor impairment, discontinuation syndrome Adverse reactions: somnolence/sedation, dizziness, constipation, blurred vision	Trazodone is sometimes used as a sleep aid in low doses, generally 25 or 50 mg. Because of reports of priapism, its use in adolescent boys is limited.

C/A, children and adolescents.

### Anxiolytics

Two benzodiazepine anxiolytics—lorazepam (short-acting) and clonazepam (long-acting)—are commonly prescribed in children and adolescents. Because dependence may develop with long-term benzodiazepine treatment, they are for short-term use only.

Benzodiazepines may be used before painful or stressful medical procedures. They can be used for short-term treatment of anxiety and distress following an acute traumatic incident or while waiting for an SSRI to have an effect. Also, benzodiazepines are used as an adjunctive treatment of schizophrenia.

Benzodiazepines are generally well tolerated. Sedation is the most common concerning adverse event.

Daytime drowsiness can be dangerous when operating a motor vehicle or machinery. Other concerning side effects are unlikely if benzodiazepines are used in the short term and at appropriately low doses.

### Sleep Aids

Insomnia is a common complaint in children with ADHD, anxiety, depression, and other disorders. In general, treatment of the primary psychiatric disorders plus counseling or behavioral approaches to improving sleep hygiene will relieve the insomnia. If not, further evaluation is warranted. Although research data are lacking, various medications are used to treat insomnia in children and adolescents,

especially those with ADHD or autism spectrum disorders associated with sleep problems. Two potential sleep aids, which are among the most commonly used in children, are included here.

Trazodone is an antidepressant approved for treatment of MDD in adults. It is sometimes used in low doses to treat insomnia in adolescents (and adults). Its mechanism of action is not well understood, but its major effect is thought to be on the serotonergic system. The adverse effects profile of trazodone is similar to that of the SSRIs, but trazodone is also associated with priapism, which may limit its use in adolescent boys.

Melatonin is a hormone produced in the pineal gland that is available over the counter, but not by prescription (and, therefore, is not included in Table 62-8). It can reduce initial insomnia. It is not recommended for long-term use. Studies, primarily in adults, indicate melatonin is effective for only 2 to 3 weeks.

Of note, ramelteon, a relatively new FDA-approved sleep aid that is not commonly prescribed for children, is the first in a new class of sleep aids that are melatonin receptor agonists with high affinity for MT1 and MT2 receptors.

## INDIVIDUAL STATE PROGRAMS FOR IMPROVING PRESCRIBING TO CHILDREN AND ADOLESCENTS

In response to recent federal guidelines, all states in the United States are developing programs to monitor psychotropic medications prescribed to children and adolescents. Specific mandates require child welfare and Medicaid agencies to work collaboratively regarding children in foster care and state custody, for whom psychotropic medications are prescribed at disproportionately high rates. These programs range from consultation models promoting collaboration among providers to drug utilization review processes that restrict access when certain criteria are not met. These programs are too new to support a comprehensive assessment of their effect on children, families, and physicians.

## DISRUPTIVE BEHAVIOR AND AGGRESSION

This chapter has focused on the 3 common medication-responsive disorders identified by the AAP Task Force on Mental Health as potentially managed by pediatricians independently. Symptoms of disruptive behavior and aggression also commonly present to pediatricians and may be manifestations of oppositional defiant disorder, conduct disorder, or other behavioral conditions. These disorders were not addressed in this chapter because they typically require comanagement with a mental health specialist and because there is considerable controversy regarding whether medication, targeted at aggression or disruptive behavior *only*, is an appropriate part of a comprehensive treatment plan.

## SUMMARY

Because of the high prevalence of mental health disorders, pediatricians commonly encounter children whose care may involve assessment for, or treatment

### BOX 62-4 Resources for Clinicians

- Additional information about pediatric psychopharmacology can be found at the Johns Hopkins Bloomberg School of Public Health Center for Mental Health Services in Pediatric Primary Care Web site ([web.jhu.edu/pedmentalhealth/index.html](http://web.jhu.edu/pedmentalhealth/index.html)).
- Children in the child welfare system may have unique needs for therapy treatment. Providers can access a Web site to review the evidence base for psychosocial interventions specifically evaluated for children in child welfare (California Evidence-Based Clearinghouse for Child Welfare at [www.cebc4cw.org](http://www.cebc4cw.org)). This information can be used to guide referrals for psychosocial therapy.
- The National Network of Child Psychiatry Access Programs is a consortium of more than 25 state programs that provide collaborative consultative access to child psychiatry expertise ([www.nncpap.org](http://www.nncpap.org)).
- The National Institute of Mental Health life-charting method facilitates prospective tracking of medication adherence, mood symptoms (activation vs depression), sleep, suicidality, and new stressors ([www.cqaimh.org/pdf/tool\\_edu\\_moodchart.pdf](http://www.cqaimh.org/pdf/tool_edu_moodchart.pdf)).
- The US Department of Agriculture Web site has resources for tracking diet and activity ([www.supertracker.usda.gov/default.aspx](http://www.supertracker.usda.gov/default.aspx)).
- The Centers for Disease Control and Prevention Web site has a simple body mass index calculator ([apps.nccd.cdc.gov/dnpabmi](http://apps.nccd.cdc.gov/dnpabmi)).

with, psychotropic medication. The AAP has released recommendations that pediatricians achieve competence in care of children with ADHD, anxiety, and depression—conditions that may, in some instances, benefit from medication. Moreover, pediatricians may encounter children for whom psychotropic medications are prescribed by behavioral health or other specialty providers and who may require monitoring by pediatricians for therapeutic benefit and potential side effects. Thus, an understanding of pediatric psychopharmacology is necessary for primary care pediatric practice. This chapter has proposed a conceptual framework and general guidance for decision making about prescribing and monitoring psychotropic medications in pediatric primary care. There are also numerous resources for pediatricians available online, including those listed in Box 62-4.

## Chapter 63

## PREOPERATIVE ASSESSMENT

Sarah Tariq, MD; Jayant K. Deshpande, MD, MPH

### INTRODUCTION

Ambulatory or same-day surgery provides significant medical, psychological, and economic benefits to children and their families. Hospitals also benefit from the reduced need for beds, lower infection rates, and lower costs. Moreover, pediatric anesthesia is no longer confined to the operating room, and increasingly children receive anesthesia and deep sedation in other settings. The ability to provide safe anesthesia for outpatients in environments outside the operating room and new technologies have also boosted the use of diagnostic imaging such as magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET) scans.

These benefits also pose challenges because of the limited time available for the anesthesiologist to

evaluate the child before the procedure. Often, the anesthesiologist may see the patient for the first time on the day of the procedure. Optimum preoperative or preprocedural assessment, therefore, depends on the effective screening of patients by the primary care physician (PCP). The PCP's assessment serves as a first screen for identifying possible risk factors that could lead to complications during anesthesia and surgery.

The goals of this chapter are:

- To enable the PCP to identify medical concerns that are relevant to the anesthesiologist.
- To help the PCP identify the common risks of anesthesia and recognize factors that can lead to adverse events.
- To discuss the optimal preparation of children for surgery for selected conditions.
- To emphasize the importance of a multidisciplinary approach in formulating a care plan for the perioperative child.
- To advocate the implementation of a quality improvement initiative to make processes safer and more efficient, resulting in better utilization of resources while providing the highest quality of care for children.

## IMPORTANCE OF A THOROUGH PREOPERATIVE ASSESSMENT

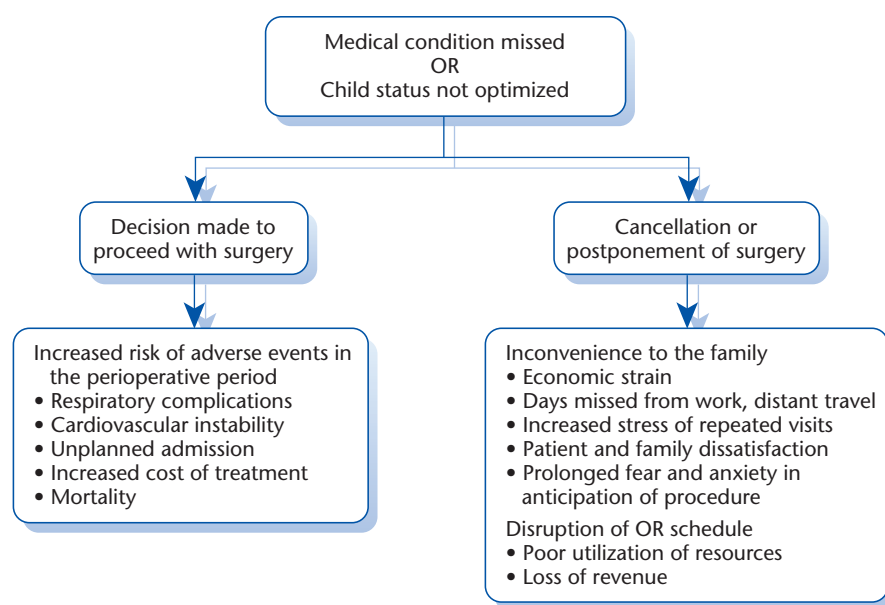

A thorough preoperative assessment is crucial for identifying potential risk factors and optimizing the child's clinical condition, particularly for children with complex medical problems. Inadequate patient preparation before surgery can lead to perioperative complications or to the cancellation of surgery. The last-minute cancellation of surgery has economic and emotional implications for patients and their families. In fact, cancellation of surgery affects all involved—the patients, their families, the physicians, and the

hospital. Common causes of cancellation of surgery are listed in Box 63-1.

An upper respiratory tract infection was cited by Tait and colleagues as the most common cause of same-day cancellation of pediatric surgery. An incomplete medical evaluation was found to be one of the main avoidable causes of day of surgery cancellation in a study by Trentman and colleagues. Another study performed at an Australian pediatric hospital also established that the most common reason for day of surgery cancellation was a medically unfit patient. A comprehensive preoperative evaluation of patients can identify children who need further investigations and children who require optimization of their medical condition before surgery. Patient safety can be severely compromised if a medical condition is overlooked or a decision is made to proceed with surgery despite the inadequate optimization of the child's medical condition. (See Figure 63-1.)

### BOX 63-1 Common Causes of Day-of-Surgery Cancellations

- Upper respiratory tract infections
- Fever
- Lack of intensive care unit (ICU) beds
- Inadequate preoperative investigations
- Medically unfit patients
- NPO (nil per os, nothing by mouth) violations
- Patient nonarrival
- Change in patient's clinical condition
- Cancellation by parents

**Figure 63-1** Effects of inadequate preoperative preparation.

## ANESTHESIA RELATED ADVERSE EVENTS

The risks associated with anesthesia depend on the age and physical condition of the child, the type of surgical procedure, and the choice of anesthesia technique (see Figure 63-2). In a large pediatric anesthesia data review by Cohen and colleagues, neonates were found to have the highest risk for perioperative adverse events. This review also established nausea and vomiting as common complications for children older than 5 years and revealed an overall 35% risk of adverse events in children undergoing anesthesia (as compared to 17% for adults). Another prospective study by Tired and colleagues established a mortality risk of 43 per 10,000 anesthetics in infants younger than 1 year, decreasing to 5 per 10,000 anesthetics in the second year of life.

Some potential anesthetic complications are listed in Box 63-2.

### Pediatric Perioperative Cardiac Arrest Registry

The Pediatric Perioperative Cardiac Arrest (POCA) registry was created in 1994 to better understand the causes, frequency, and risk factors associated with cardiac arrest in children during the perioperative period. Approximately 80 institutions in the United States and Canada voluntarily provided standardized data for each instance of perioperative cardiac arrest. Between 1998 and 2004, the POCA registry reviewed 397 reports of perioperative cardiac arrests in children; of these, 49% were deemed anesthesia related. Cardiovascular causes accounted for 41%, and respiratory issues caused 27% of the arrests, while medication-related causes accounted for 18% of all arrests.

(See Figure 63-3.) Infants and patients with severe systemic disease are at highest risk for perianesthetic mortality.

Flick and colleagues studied the occurrence of perioperative cardiac arrests in 92,881 children who received anesthesia between 1988 and 2005 at a tertiary referral center. They determined the incidence of perioperative cardiac arrest to be 2.9 per 10,000 anesthetics for noncardiac procedures versus 127 per 10,000 anesthetics for cardiac procedures. They further

### BOX 63-2 Potential Anesthetic Complications

#### MINOR COMPLICATIONS

- Sore throat
- Nausea, vomiting
- Dental trauma
- Emergence delirium, agitation

#### MAJOR COMPLICATIONS

- Respiratory: laryngospasm, bronchospasm, oxygen desaturation, hypoventilation, apnea, croup, prolonged mechanical ventilation
- Cardiac: bradycardia, hypotension, hypertension, arrhythmias, cardiac arrest
- Neurologic: delayed awakening, seizures, nerve damage, paralysis
- Allergic reactions, anaphylaxis
- Aspiration of gastric contents
- Malignant hyperthermia
- Mortality

**Figure 63-2** Morbidity and mortality from anesthesia in children. (Adapted from Olsson GL, Hallen B: Laryngospasm during anesthesia: a computer-aided incidence study of 136,929 patients. *Acta Anaesthesiol Scand.* 1984;28:567-575; and Morray JP, Geiduschek JM, Ramanmoorthy C, et al. Anesthesia-related cardiac arrest in children. *Anesthesiology.* 2000;93:6-14.)

determined that both the incidence of cardiac arrest and mortality were highest among neonates undergoing cardiac procedures. They concluded that most cardiac arrests were not attributed to anesthesia. (See Figure 63-4.) These findings are divergent from the previous accounts from the POCA data analysis.

### Pediatric Anesthesia Malpractice Closed Claims Registry

The pediatric anesthesia malpractice closed claims registry is another valuable source of information on perioperative risks in children. In this registry, 75% of pediatric claims were made for patients considered generally healthy (American Society of Anesthesiologists physical status [ASA PS] 1 and 2) when undergoing

anesthesia. The procedures most commonly cited were dental, ear, nose, throat, and maxillofacial procedures (36%) followed by abdominal procedures (17%). Although these results may be skewed by the frequency of cases performed (ASA PS 1 and 2 children are the most frequently anesthetized, and these are the most common procedures for which children are anesthetized), they suggest that procedures related to the airway are associated with an increased risk of complications and death.

The incidence of anesthesia-related adverse events has been cited as high as 75 per 1,000 anesthetics. The most common adverse events result from respiratory causes during the procedure and vomiting during the recovery period; younger children also are likely to experience respiratory adverse events in the recovery period.

Psychological stress and behavioral complications are additional adverse outcomes in the perioperative experience of the child. The principal risk factors are inadequate family preparation and the lack of preprocedure anxiolysis. Parents who have been inadequately prepared about the process exhibit significant anxiety, which has been demonstrated to be transmitted to the child. Children who experience stressful anesthetic induction often exhibit postoperative maladaptive behaviors, including enuresis, night terrors, and violent behavior. Children requiring repeated invasive procedures can develop a posttraumatic stress-like syndrome.

### The American Society of Anesthesiologists Physical Status Classification

The American Society of Anesthesiologists physical status (ASA PS) classification (Table 63-1) provides a convenient method of summarizing a patient's physical condition and may provide a means of assessing the relative risk of anesthesia. ASA PS 1 patients are healthy and have no underlying disease, whereas ASA PS 4 patients are significantly incapacitated by their underlying disease. Other factors associated with increased preoperative risk are multiple coexisting diseases and the need for emergent surgery. The anesthetic mortality rate in healthy ASA PS 1 children requiring elective surgery is probably less than 1 in 50,000.

**Figure 63-3** Causes of arrest from the Pediatric Perioperative Cardiac Arrest Registry. (From Morray JP, Bhananker SM. *Recent Findings from the Pediatric Perioperative Cardiac Arrest [POCA] Registry*. ASA Newsletter. 2005;69[6]:10-12. Reprinted with permission from the American Society of Anesthesiologists.)

**Figure 63-4** Causes of anesthesia related cardiac arrest

**Table 63-1** American Society of Anesthesiologists Physical Status Classification

CLASS	STATE	CASES
I	Healthy, normal child	
II	Child with mild systemic disease	Controlled asthma, controlled diabetes
III	Child with severe systemic disease	Active wheezing, diabetes mellitus with complications, heart disease that limits activity
IV	Child with severe systemic disease that is a constant threat to life	Status asthmatics, severe BPD, sepsis
V	Child who is moribund and not expected to survive without the procedure	Cerebral trauma, pulmonary embolus, septic shock

Adapted from American Society of Anesthesiologists, ASA physical status classification system. Available at: [asahq.org/resources/clinical-information/asa-physical-status-classification-system](http://asahq.org/resources/clinical-information/asa-physical-status-classification-system). Accessed January 6, 2016.

Children who are candidates for outpatient surgery are generally in the ASA PS 1 and 2 groups. Although initially outpatient surgery was reserved for patients belonging to ASA PS 1 and 2, ASA PS 3 patients increasingly present for outpatient procedures. Because of the increased perioperative risk to these children, direct communication between the PCP and the anesthesiologist is advised well in advance of the planned surgical procedure.

### PREOPERATIVE EVALUATION: NOT “CLEARANCE FOR SURGERY”

Preoperative evaluation of a child going for surgery is not synonymous with clearance for surgery. Clearance for surgery is an outdated concept which often does not relay significant information about a child's condition to the anesthesiologist or perioperative team. Primary care providers can play a significant role in creating a safe perioperative environment by providing an accurate assessment of the child's current medical condition and by working to optimize the child's clinical status in preparation for surgery, thus minimizing the risk to the patient in the perioperative period.

A complete preoperative evaluation comprises the following:

- A thorough history and physical examination
- Laboratory and imaging investigations when indicated
- Management/optimization of the child's medical condition
- Appropriate subspecialty consults when required
- Closed loop communication with the anesthesiologist, surgeon, and other members of the health care team regarding any abnormal findings or special needs. This is particularly required for children with complex medical problems.

### PREANESTHETIC HISTORY

The preanesthetic evaluation should focus on specific elements of the child's medical history and physical examination that may have physiologic consequences during the conduct of an anesthetic. The main concerns involve the pulmonary, cardiovascular, endocrine, hematologic, and neuromuscular systems. The

following information is important to determine the potential risks of anesthesia for each child:

- Birth history: Premature versus full term, complications at birth, neonatal clinical course (particularly respiratory, cardiovascular, and neurologic issues)
- Comorbidities and understanding of the child's optimum clinical condition (for example, best pulmonary functions achievable for a child with asthma on appropriate therapy)
- Current acute illness (eg, upper respiratory infection, asthma exacerbation)
- Developmental delays, autism, or other behavioral-communicative disorders
- Bleeding diathesis (eg, hemophilia, von Willebrand disease, sickle cell disease)
- Allergies, especially to drugs, food, latex
- Current and recent medications
- Child's weight
- Previous surgical procedures and any adverse events
- Previous anesthetics: Ease or difficulty with intravenous access and airway instrumentation, complications
- Family history of anesthesia complications
- Family history of malignant hyperthermia
- History of smoking, alcohol intake, and substance abuse

The remainder of this chapter discusses issues pertinent to the preoperative assessment in a systematic fashion, identifying critical factors that would be of importance to the anesthesiologist caring for children.

### RELEVANT ASPECTS OF THE PHYSICAL EXAMINATION

The physical examination should determine the patient's general state of health with the aim of specifically discovering any conditions that might complicate anesthesia.

#### General Appearance, Weight, and Vital Signs

The PCP should note the general body habitus, height, and weight (in kilograms). Accurate weight measurement is essential because anesthetic drug dosing is calculated by weight. Preoperative vital signs, including temperature, respiratory rate, heart rate, and blood pressure, should be recorded.

## Mallampati Signs as Indicators of Difficult Intubation

**Figure 63-5** Mallampati airway classification.

### Airway Examination

A thorough examination of the head and neck is essential. The airway examination is especially important. Even when the airway is normal, the PCP should make specific note of adequacy of mouth opening, neck mobility, and the presence of loose teeth. Normal mouth opening, mandibular size, and neck mobility are fundamental to the success of intubation using the most common technique, direct laryngoscopy. Abnormalities in these parameters, either congenital (micrognathia) or acquired (jaw immobility caused by infection, trauma, or irradiation), can lead to great difficulty with intubation, which, if unexpected, can lead to adverse airway events and imperil the life of the child. Alerting the anesthesiologist to these abnormalities helps with appropriate advanced preparation if special anesthetic techniques and equipment (eg, fiberoptic bronchoscope, glidescope, intubating laryngeal mask airway [LMA], etc) are needed for airway management.

Important components of airway examination include:

- Mallampati classification (see Figure 63-5)
- Mouth opening
- Thyromental distance
- Cervical range of motion
- Mandibular or maxillary hypoplasia
- Microsomia
- Presence of loose teeth

The presence of a short neck, large tongue, and a small mandible, midfacial hypoplasia, or maxillary hypoplasia all can lead to difficulty with intubation. In addition to difficulty with intubation, such children may have airway obstruction on induction of anesthesia and difficulty with ventilation. Many congenital syndromes are associated with anatomic abnormalities that may cause difficulty with intubation (see Box 63-3).

### BOX 63-3 Select Conditions Likely to Be Associated With Difficult Airway

- Pierre-Robin syndrome
- Treacher-Collins syndrome
- Mucopolysaccharidosis
- Down syndrome
- Klippel-Feil syndrome
- Choanal atresia (CHARGE syndrome)

### Cardiovascular and Pulmonary Examination

The cardiovascular and respiratory systems are of particular importance because of the significant alterations that take place under anesthesia. For example, children who have significant chest wall or thoracic deformities (eg, severe scoliosis, dwarfism) can have marked cardiorespiratory compromise, exhibited as decreased lung volumes and pulmonary function, and can have myocardial strain evident on electrocardiogram (ECG) or echocardiogram. These children are at a higher risk for intraoperative complications and prolonged postoperative mechanical ventilation. An assessment of preoperative pulmonary and myocardial function is warranted and enables the anesthesiologist to design the optimal anesthetic plan.

### Neuromuscular Examination

An evaluation of the child's neurologic status includes an assessment of the type and extent of preexisting deficits. The child's baseline mental status, especially in children who are developmentally delayed or non-verbal, is important in gauging the child's responses

under anesthesia and in evaluating the progress of the child's recovery afterward. Preexisting neuropathies and neurologic deficits should be documented to differentiate from possible complications from positioning during surgery and regional anesthesia. In particular, muscular dystrophies, myotonic dystrophy, congenital myotonias, and mitochondrial diseases may be associated with life-threatening conditions (malignant hyperthermia, severe hyperkalemia, severe myotonia).

Findings on physical examination that raise concerns for the anesthesiologist include:

- Morbid obesity
- Limited mouth opening, recessed chin, short neck, large tongue, or a small mandible
- Wheezing, rhonchi, or rales on auscultation
- Low baseline room air oxygen saturation
- Presence of a murmur
- Cyanosis
- Fever
- Signs of severe dehydration/hypovolemia, including delayed capillary refill
- Signs of increased intracranial pressure (positional headaches, sundowning, recurrent vomiting, nystagmus)
- Ill appearance
- Poor weight gain
- Excessive bleeding or bruising

## NOTHING BY MOUTH: THE PREOPERATIVE FAST

Patients with large volumes of acidic gastric contents are at risk for pulmonary aspiration and significant morbidity. Because this risk of pulmonary aspiration in healthy children is less than 0.05%, the practice of NPO (*nil per os*) after midnight has been abandoned. The American Society of Anesthesiologists has revised the preoperative fasting guidelines for all age groups (Table 63-2).

Children are encouraged to drink clear liquids to minimize the anxiety, hypovolemia, and possible hypoglycemia that may result from a prolonged preoperative fast. Necessary medications are administered with a sip of water on the morning of surgery. Healthy children are allowed to drink clear fluids until

2 hours preoperatively; breastfed infants can feed until 4 hours preoperatively; nonhuman milk and formula can be consumed until 6 hours before the scheduled procedure. Despite the suggestion of the acceptability of a 6-hour fast after a light meal, most solid food meals have a high fat content, which delays gastric emptying. Because of these factors, many pediatric anesthesiologists require a fast of 8 hours after solid food for elective surgery. Gum chewing increases gastric fluid volume at least two-fold, without clinically significant important buffering of the pH of the gastric fluid, and therefore is generally proscribed in the preoperative period.

Parents often are confused about what constitutes a clear liquid during the preoperative period. Examples of clear liquids include water, clear fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

## PREOPERATIVE LABORATORY EVALUATION

Routine laboratory studies are not required in children for most procedures. Laboratory tests are performed when children have certain clinical conditions or for certain high-risk procedures. Routine preoperative chest radiographs also are not necessary in well children, because they do not detect abnormalities of major anesthetic or surgical consequence.

### Hemoglobin Determination

Serum hemoglobin (Hgb) or hematocrit (Hct) is the most commonly requested preoperative laboratory test. Because the incidence of previously undetected anemia in children undergoing elective surgery is extremely low (0.29%), routine determination of Hgb and Hct is not necessary if the results of studies performed previously as part of well-child care have been normal. A preoperative Hgb or Hct is useful in children with chronic medical illnesses and those about to undergo procedures with the potential for significant blood loss. It may be useful to measure preoperative Hgb in infants younger than 6 months because the physiologic nadir of red blood cell production may cause the Hgb level to decrease to as low as 7 g/dL. Importantly, in infants who were born prematurely, Hgb levels of less than 10 g/dL have been associated with an increased incidence of postoperative apnea. Children of African or African American ethnicity who have not had a Hgb or Hct determination after 6 months of age should have Hgb or Hct determined. Preoperative coagulation studies (prothrombin time, partial thromboplastin time, and platelet count) are useful in children undergoing procedures with an increased risk for intraoperative or postoperative bleeding (eg, posterior spinal fusions, intracranial procedures), even when no history of a bleeding disorder in the child or the child's family exists.

### Electrolyte Abnormalities

Electrolyte abnormalities of any consequence are extremely rare in healthy children; preoperative screening for such deviations is usually unhelpful, and routine preoperative testing is not indicated. However, serum

**Table 63-2**

**NPO Guidelines**

INGESTED MATERIAL	MINIMUM FASTING PERIOD
Clear liquids	2 hours
Breast milk	4 hours
Infant formula	6 hours
Nonhuman milk	6 hours
Light meal	6 hours

From Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures. An updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114:495–511.

electrolytes should be evaluated in children with underlying conditions such as renal insufficiency or in those who are taking diuretics, angiotensin-converting enzyme inhibitors, or other medications that increase the likelihood of an abnormal result. Electrolytes should also be determined in children whose feeding is limited to enteral (nasogastric or gastrostomy tube) feedings or parenteral nutrition.

### Pregnancy Testing

Exposure to anesthetics during pregnancy may be associated with chromosomal abnormalities in the fetus. Therefore, the routine pregnancy screening before anesthesia of all menarcheal females is performed in many institutions. The incidence of a positive pregnancy test result in the preoperative adolescent population ranges from 0.5% to 1.2%. At some institutions it is mandatory to obtain a pregnancy test before anesthesia on all females older than 10 years, using point-of-care urine testing on the day of surgery. When a positive result is obtained the surgical procedure is canceled, and a pediatric social worker is consulted to counsel the patient and family to address the ramifications of the positive test result.

### Miscellaneous Testing

Although the healthy child needs almost no preoperative laboratory tests, the situation is entirely different for children who have the presence or history of an underlying clinical abnormality. For example, a chest radiograph in a child who has a history of chronic aspiration or lower airway disease may point to chronic parenchymal disease or other abnormalities. A child with cardiovascular disease who is taking digoxin or another cardiac medication should have serum sodium, potassium, and digoxin levels measured. An ECG is warranted in a child who has obstructive sleep apnea syndrome (OSAS), bronchopulmonary dysplasia (BPD), congenital heart disease (CHD), or severe scoliosis. Children being treated with anticonvulsants should have serum levels of these medications checked to ensure that they are within the therapeutic range. In these and similar circumstances, preoperative testing is aimed at detecting and quantifying underlying abnormalities associated with known disease that can lead to life-threatening complications during anesthesia.

### Pulmonary Function Tests

Pulmonary function tests are rarely necessary preoperatively in patients with uncomplicated asthma but may be useful in predicting if children who have pulmonary or thoracic cage abnormalities such as scoliosis are at increased risk for anesthetic complications and postoperative respiratory insufficiency. The most common preoperative pulmonary studies are pulse oximetry, forced vital capacity (FVC), and forced expiratory volume in 1 second (FEV1). The absolute values obtained and the ratios of (FEV1/FVC) are useful predictors of the need for postoperative mechanical ventilation among children at risk (eg, in kyphoscoliosis). However, the accurate measurement of FEV1 and FVC requires patient cooperation. Obtaining reliable results in children younger than 6 years is usually not possible.

## PERIOPERATIVE MEDICATION MANAGEMENT

Children may receive medications regularly for many illnesses. Most medications should be given at their usual doses up to and on the day of surgery (see Box 63-4). Some drug regimens need to be adjusted in the perioperative period (see Box 63-5 and Box 63-6).

The decision to stop or continue anticoagulants before surgery is governed by:

- The child's medical condition
- Indication for anticoagulation
- The nature of the surgical procedure

It is prudent to consult with the surgeon, cardiologist, or other involved physicians to guide the decision-making process by weighing the risks of discontinuing the anticoagulant versus the obvious benefit of reduced bleeding complications in the perioperative period. Children taking aspirin or clopidogrel for coronary stents or children who are at increased risk for vascular complications should be evaluated by a cardiologist or other consultant before surgery. Aspirin or clopidogrel should never be discontinued in such cases unless specifically directed by the cardiologist. If deemed appropriate by the cardiologist or another consultant involved, the recommended time frames for discontinuation of medications that can alter hemostasis are given in Box 63-7.

### BOX 63-4 Medications to Continue in the Perioperative Period Including the Day of the Surgery

β-blockers  
 Calcium channel blockers  
 Antiarrhythmics  
 Nitrates  
 Clonidine  
 Digoxin  
 Asthma medications (care may even be escalated 1–2 weeks before surgery)
 

- β-agonists
- Bronchodilators
- Steroid inhalers

 Seizure medications  
 Reflux medications
 

- Proton pump inhibitors
- H<sub>2</sub>-receptor antagonists

 Selective serotonin reuptake inhibitors  
 Insulin (see section on diabetes)  
 Levothyroxine  
 Antithyroid agents  
 Glucocorticoids  
 Benzodiazepine  
 Opioids  
 Tricyclic antidepressants  
 Antipsychotics

### **BOX 63-5 Medications to Continue Until the Day Before Surgery But Hold the Day of the Surgery**

Oral hypoglycemic agents  
Diuretics  
Angiotensin converting enzyme inhibitors and angiotensin receptor blocking drugs (ARBs)

### **BOX 63-6 Medications to Discontinue Preoperatively**

Aspirin (7–10 days)  
Nonsteroidal anti-inflammatory drugs (NSAIDs) (2–3 days)  
Oral contraceptive pills (OCP) (4–6 weeks)  
Monoamine oxidase inhibitors (MAOIs) (2 weeks)  
Hormone replacement therapy (HRT) (4–6 weeks [in conjunction with OCPs])  
Herbal preparations (2 weeks [ASA recommendations])

### **BOX 63-7 Hemostasis Altering Medications to Discontinue Preoperatively**

Aspirin (7 days)  
Coumadin (5 days)  
Clopidogrel (7 days)  
Ticlopidine (10–14 days)  
Dipyridamole (7 days)

Similarly, there is disagreement regarding the decision to continue oral contraceptive pills in the perioperative period. These medications are associated with an increased risk of thromboembolism, so the decision to stop these medications should be weighed against the risk of unwanted pregnancy. For major surgery with high risk of thromboembolism, most experts recommend discontinuing oral contraceptive pills at least 4 weeks before surgery. Most experts favor the withdrawal of hormone replacement therapy 4 to 6 weeks before surgery because of the higher risk of thromboembolism with this therapy.

## **PREOPERATIVE ASSESSMENT AND MANAGEMENT OF SPECIFIC CONDITIONS**

### **Respiratory**

General anesthesia affects pulmonary dynamics profoundly and adversely. Box 63-8 summarizes the effects of general anesthesia on the pulmonary system.

In the setting of preexisting respiratory disease, these effects are exaggerated and can lead to potentially

### **BOX 63-8 Effects of General Anesthesia**

- Decreased functional residual capacity by 15%–20% (this effect can persist for hours after surgery)
- Decreased lung and chest wall compliance
- Increased ventilation perfusion mismatch (V/Q mismatch: increased dead space, increased intrapulmonary shunting)
- Inhibition of hypoxic pulmonary vasoconstriction
- Hypoventilation
- Exacerbation of airway reflexes (laryngospasm, bronchospasm, and increased secretions)
- Decreased contractility of respiratory muscles
- Decreased ciliary clearance
- Depression of central respiratory response to hypoxia and hypercapnia

### **BOX 63-9 Possible Anesthetic Complications in Children with URI**

- Laryngospasm: can lead to negative pressure pulmonary edema
- Bronchospasm: can make ventilation difficult
- Oxygen desaturation
- Severe coughing
- Breath holding
- Post extubation croup
- Unplanned hospital admission
- Prolonged need for mechanical ventilation

life-threatening complications in the perioperative period. The assessment and optimization of a child's pulmonary status is of paramount importance before elective surgery.

### **Upper Respiratory Tract Infection**

*"It's just a cold, why can't my child have surgery?"*

Often pediatric anesthesiologists are faced with the challenge of deciding whether a child with an active or recent upper respiratory tract infection (URI) should undergo anesthesia. No greater difference in perspective exists between the PCP and the pediatric anesthesiologist than in the diagnosis of a URI. To the PCP, the diagnosis is usually one of reassurance. To the anesthesiologist, a URI is a diagnosis that mandates a careful risk, benefit, and consequence analysis (see Box 63-9).

Children with active or recent URI are more likely to have episodes of laryngospasm, oxygen desaturation, bronchospasm, severe coughing, and breath holding during anesthetic induction and emergence. Independent risk factors for adverse perioperative respiratory events in the setting of an active or recent URI are summarized in Box 63-10.

The incidence of perioperative respiratory events is increased 7-fold in children with URI and 11-fold if the child is intubated. The risk of airway complications remains high for up to 6 weeks after a URI, probably

### **BOX 63-10 Risk Factors for Adverse Perianesthetic Respiratory Events Occurring During Acute and Recent Upper Respiratory Tract Infection**

- Age younger than 5 years
- Copious secretions
- Endotracheal intubation required for procedure
- History of reactive airway disease
- History of prematurity
- Parental smoking history
- Upper respiratory infection within the previous 4 weeks
- Wet cough
- Wheezing

Derived from Tait AR, Malviya S, Voepel-Lewis T, et al. Risk factors for perioperative adverse respiratory events in children with upper respiratory tract infections. *Anesthesiology*. 2001;95(2): 299–306.

as a result of altered airway reactivity. Children with URIs undergoing elective cardiac surgery have a 4-fold increased incidence of airway complications at induction of anesthesia, a 2-fold increased incidence of postoperative respiratory complications, a 5-fold increase in postoperative bacterial infections, and an increased risk of an extended stay in the intensive care unit. Mortality during or after administration of an anesthetic in a child with a URI has rarely been reported. Airway events, however, were responsible for almost 30% of all pediatric anesthetic deaths in the most recent summary of pediatric perioperative cardiac arrest registry data. The most common events leading to cardiac arrest in this category are laryngospasm, airway obstruction, inadequate oxygenation, inadvertent extubation, difficult intubation, and bronchospasm, some of which might be related to URI.

Interestingly, several studies have found no significant increase in respiratory complications among children anesthetized during an acute URI, which has led some researchers to advocate against canceling surgery for these children. The physiologic, psychological, and financial implications of delays in surgery must be weighed against the risks of increased perioperative complications of anesthetizing a child who has a URI. Children with systemic manifestations, such as a temperature greater than 101.3°F (38.5°C), purulent nasal discharge, and lower respiratory symptoms such as productive cough, crackles, wheezes, or positive chest radiograph findings, should have the surgical procedure delayed until 4 to 6 weeks after the resolution of symptoms. Surgery and anesthesia can usually be performed safely in children who have none of these symptoms, particularly if they do not require endotracheal intubation. Even in the absence of these symptoms in children with a history of recent URI, adverse events are still possible. Parents should be informed of this possibility and that intra- or postoperative treatment (eg, nebulization of  $\beta$ -agonist for wheezing) may be required.

Parents should also be told that increased adverse perioperative respiratory events occur in children exposed to cigarette smoke at home. (See Figure 63-6.)

### **Asthma**

Asthma is characterized by:

- Chronic inflammation of airway mucosa
- Airway hyperreactivity
- Expiratory airflow obstruction

Many procedures performed routinely during anesthetic management, most notably laryngoscopy and intubation, are potent and intense stimuli that produce bronchospasm in the child with reactive airways. An intraoperative bronchospasm is frightening, is challenging to treat, and can be catastrophic. Ventilation is difficult if not impossible, and may result in hypercapnia, acidosis, hypoxia, cardiovascular collapse, and death. Fortunately, these adverse events need not happen. Maximal preoperative optimization of a child's medical management may prevent, or at the least limit, all of the perioperative complications of asthma. In general, asthma medical therapy must be escalated preoperatively even in asymptomatic children or children with well-controlled asthma to limit or prevent intraoperative bronchospasm. Short courses of corticosteroids in particular are extremely effective in preventing perioperative wheezing, even in patients who have severe asthma. Thus, children who take asthma medications only as needed should use their inhaled  $\beta$ -agonists or oral medications 3 to 5 days preoperatively. Children taking medications on a long-term basis (oral or inhaled) should have steroids added in doses that are normally used for an acute exacerbation. Finally, the child with difficult-to-control asthma and who takes bronchodilators and steroids regularly requires intensification of therapy in preparation for surgery. Under no circumstances should asthma therapy be de-escalated or stopped before surgery.

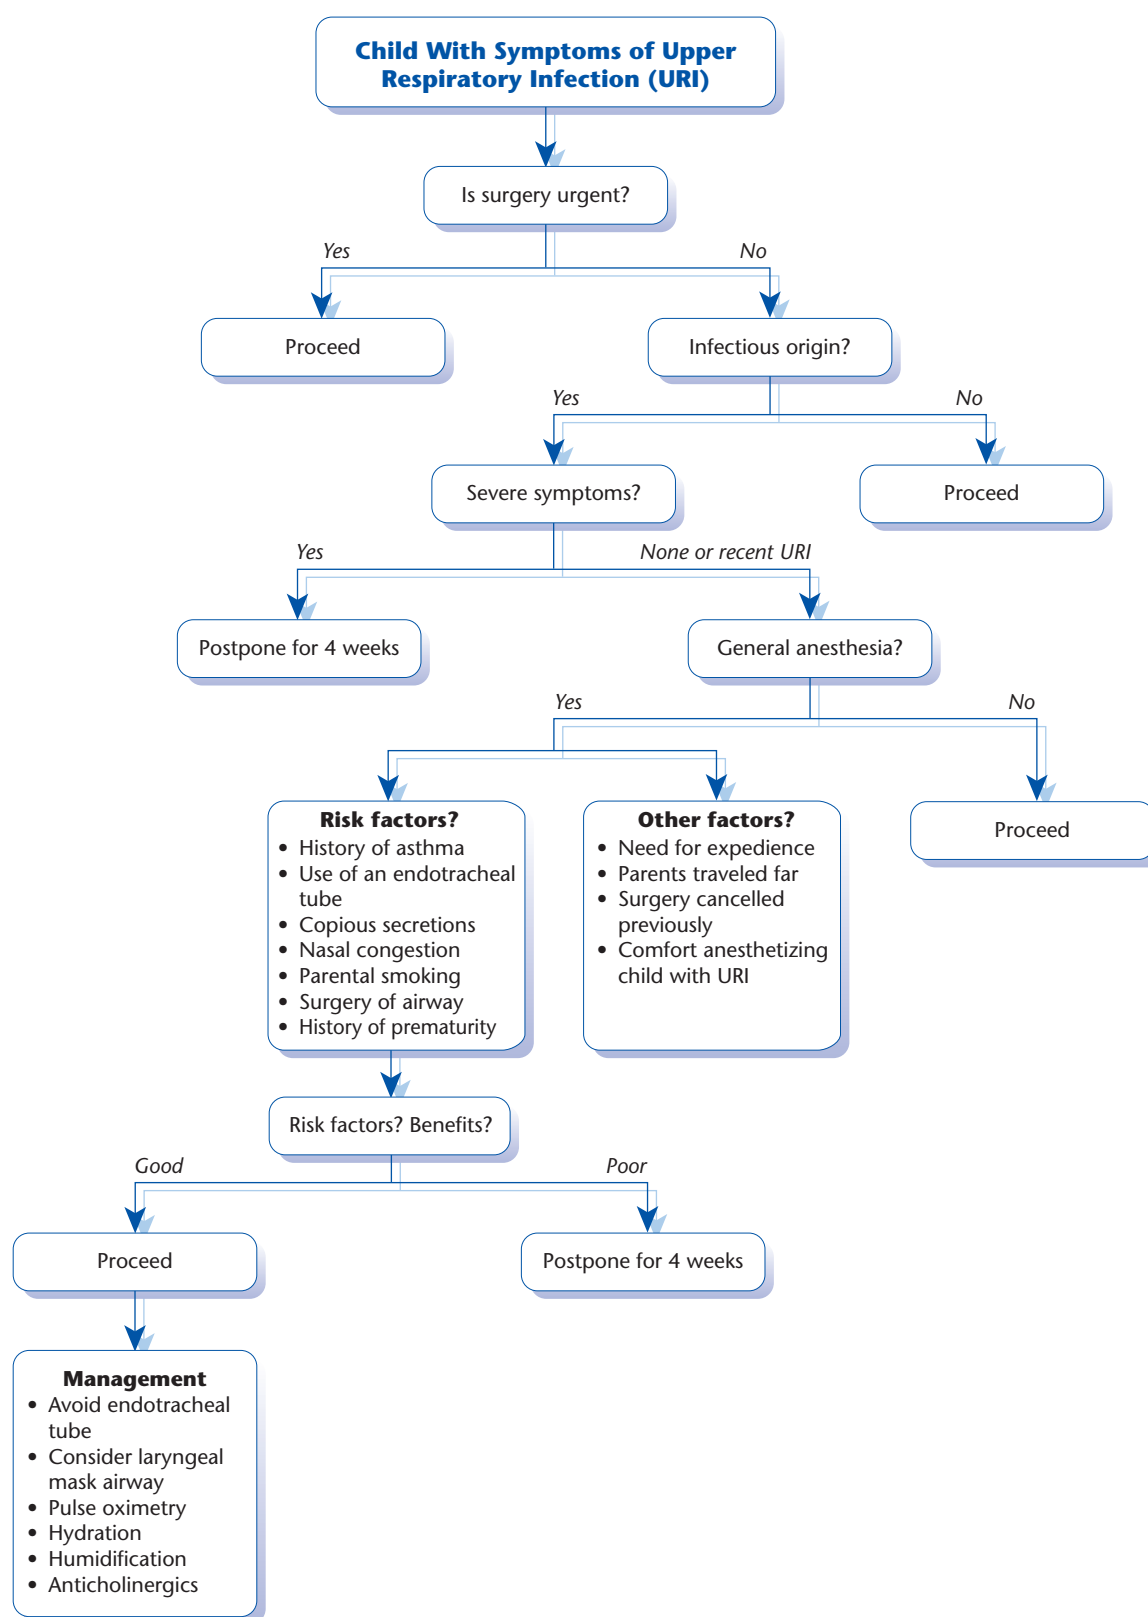

Elective surgery should never be performed in a child who is wheezing actively or who has had a recent asthma exacerbation.

### **Cardiovascular Disease**

A good evaluation begins with a thorough history and physical examination. Compromising this aspect of patient care can lead to adverse outcomes. General anesthesia has several effects on the cardiovascular system (see Box 63-11) that collectively lead to hypotension and decreased cardiac output.

The effects of general anesthesia on the cardiovascular system are more pronounced in the presence of underlying cardiac disease, and the induction of general anesthesia in patients with cardiovascular disease can lead to severe hemodynamic instability and even cardiovascular collapse. Therefore, identifying children with cardiac disease and optimizing their medical condition is of the utmost importance before any elective procedure. Cardiac conditions encountered in the pediatric population include:

- CHD: structural defects and intracardiac shunts (cyanotic, noncyanotic)
- Cardiomyopathy
- Valvular heart disease
- Hypertension

**Figure 63-6** Preoperative decision making in children with upper respiratory infection symptoms. (From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory infection: still a dilemma? *Anesth Analg*. 2005;100:59–65. Reprinted with permission of Wolters Kluwer Health, Inc.)

- Pulmonary hypertension
- Congestive heart failure
- Arrhythmias

The following signs and symptoms may indicate serious underlying cardiac disease and warrant further investigation.

In infants:

- Diaphoresis with feeding or crying (times of increased cardiac demand)
- Poor feeding
- Tachypnea
- Cyanosis/cyanotic spells
- Failure to thrive, poor weight gain
- Certain congenital syndromes (see Table 63-3)

In older children:

- Poor exercise tolerance
- Chest pain
- Palpitations
- Dyspnea on exertion
- Family history of sudden deaths

The finding of a new murmur on examination is concerning. Fortunately, most murmurs (75%–90%) are insignificant or “innocent” and do not require further cardiac workup. Innocent murmurs are also

known as “functional” or “flow” murmurs and have the following characteristics:

- Nature: soft, vibratory, or musical
- Timing: Early systole, an *innocent murmur is never diastolic* (except for a venous hum that is heard during both systole and diastole)
- Grade: Typically not greater than 2/6 in intensity
- Exacerbated during times of increased cardiac output (eg, fever, infection, anemia, and anxiety)

Furthermore, children with innocent murmurs are asymptomatic, have an age-appropriate growth pattern and exercise tolerance, and a normal electrocardiogram. Examples of innocent murmurs include Still’s murmur, pulmonary flow murmurs, venous hum, and the arterial supraclavicular bruit. However, any murmur of questionable status should be evaluated further as it can indicate an intracardiac shunt or valvular heart disease. Moreover, many pediatric syndromes are associated with cardiac anomalies. Children with such syndromes should routinely be screened for the presence of occult cardiac anomalies.

All children who present with signs and symptoms that suggest cardiac disease should undergo a thorough cardiac evaluation before elective surgery, including:

- Hgb and Hct
- Chest radiograph
- ECG
- Echocardiogram
- Consultation with a pediatric cardiologist

In the presence of established heart disease, children should have a recently documented evaluation by the cardiologist (within a year) stating recommendations for perioperative management (the need to continue cardiac medications, etc) and whether infective endocarditis (IE) prophylaxis is required.

### **Infective Endocarditis Prophylaxis**

The American Heart Association guidelines on IE were revised in 2007 (see Box 63-12). These guidelines are

### **BOX 63-11 Effects of General Anesthesia on the Cardiovascular System**

- Slowing of sinoatrial node conduction
- Decreased systemic vascular resistance
- Decreased myocardial contractility

#### **NET EFFECT**

- Hypotension
- Decreased cardiac output ( $CO = HR \times SV$ )

**Table 63-3**

### **Syndromes, Associations, and Disorders With Concomitant Cardiac Involvement**

Down syndrome (trisomy 21)	ASD, VSD, TOF, PDA
DiGeorge syndrome	Conotruncal anomalies
Edwards syndrome (trisomy 18)	VSD, polyvalvular disease, high incidence of CHF
Patau (trisomy 13)	PDA, septal defects, valve abnormalities, dextrocardia
Williams syndrome <sup>a</sup>	Valvular and supravalvular aortic stenosis (which can be critical), coarctation of aorta, coronary artery stenosis
Turner syndrome	Coarctation of aorta, bicuspid aortic valve, HTN
Noonan syndrome	Pulmonary valve dysplasia/stenosis
Marfan syndrome	MVP and mitral regurgitation, ascending aortic dilatation, increased risk for aortic dissection
VACTERL association	VSD, ASD, TOF
CHARGE association	Conotruncal and aortic arch anomalies
Tuberous sclerosis	Cardiac rhabdomyoma, conduction defects
Duchenne muscular dystrophy	Cardiomyopathy
Becker muscular dystrophy	LV dysfunction, cardiomyopathy and heart failure later in life
Mucopolysaccharidases (Hurler, Hunter, Pompe)	Valvular heart disease, cardiomyopathy

<sup>a</sup>Very high risk for perioperative complications

ASD, atrial septal defect; PDA, patent ductus arteriosus; TOF, tetralogy of fallot; VSD, ventricular septal defect.

### BOX 63-12 Highlights of the 2007 American Heart Association Guidelines for the Prevention of Infective Endocarditis

- Bacteremias resulting from activities of daily living are more likely to result in IE than bacteremias from dental procedures
- Even if prophylaxis were completely effective, only an extremely small number of cases of IE may be prevented with antibiotic prophylaxis
- Recommendation of antibiotic prophylaxis is not based exclusively on an increased lifetime risk of developing endocarditis
- Prophylaxis of IE is recommended only in patients with conditions that put them at the highest risk of adverse outcomes should they develop endocarditis
- Antibiotic prophylaxis is no longer recommended for patients with other forms of cardiac conditions not listed
- Antibiotic prophylaxis is recommended only for the dental procedures that involve manipulation of the gingival tissues or periapical tissue of teeth or perforation of the oral mucosa in patients with underlying high-risk cardiac conditions
- Antibiotic prophylaxis is recommended for procedures involving the respiratory tract or infected skin, skin structures, or musculoskeletal tissues only in patients with the underlying cardiac abnormalities outlined
- Antibiotic prophylaxis exclusively to prevent endocarditis is not recommended for gastrointestinal or genitourinary tract procedures
- The recommendation regarding the procedures for which endocarditis prophylaxis was not recommended in the 1997 guidelines remains in effect, including ear or body piercing, tattooing, vaginal delivery, and hysterectomy

Modified from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis. Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2007;116(15):1736–1754. Copyright © 2007 American Heart Association. Reprinted with permission.

substantially different from previous guidelines and recommend IE prophylaxis for significantly fewer patients. Antibiotic prophylaxis is no longer necessary for genitourinary and gastrointestinal procedures. While previous (1997) guidelines called for antibiotic prophylaxis for patients in high and moderate risk categories, the 2007 guidelines recommend that only patients in the high-risk category require prophylaxis (Box 63-13).

### The Premature Infant

Infants born prematurely (<37 weeks' gestation) are at significant risk of apnea after exposure to sedative drugs and anesthetic agents. (See Figure 63-7.)

### BOX 63-13 Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis for Which Prophylaxis With Dental Procedures Is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD)<sup>a</sup>
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure<sup>b</sup>
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

<sup>a</sup>Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

<sup>b</sup>Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

From Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2007; 116(15):1736–1754. Copyright © 2007 American Heart Association. Reprinted with permission.

**Figure 63-7** Predicted probability of apnea in relation to gestational age and postconceptual age. (Cote CJ, Zaslavsky A, Downes JJ, et al. Postoperative apnea in former preterm infants after inguinal herniorrhaphy. A combined analysis. *Anesthesiology*. 1995;82:809–822. Reprinted by permission of Wolters Kluwer Health, Inc.)

This risk of apnea affects the postanesthetic care of infants born prematurely, mandating that those at risk be admitted for monitoring after the procedure. Although most apneic episodes occur within the first 2 hours after an anesthetic, apnea can be seen for up to 12 hours (Box 63-14).

A hemoglobin concentration of less than 10 g/dL increases the risk to greater than the mean for infants of all postconceptual ages.

Nonanemic infants who had been born prematurely and who have attained a postconceptual age (PCA; gestational age added to age after birth) of greater than 56 weeks have less than a 1% risk of developing postoperative apnea.

It is advisable to admit all at-risk patients (those with a PCA of younger than 60 weeks), regardless of the anesthetic technique used, to monitored, high-surveillance inpatient units for 24 hours after anesthesia and surgery. Similarly, infants born at term must be at least 1 month of age to be candidates for outpatient management because postanesthetic apnea has been reported in infants up to 44 weeks PCA. Many centers and some states (eg, Pennsylvania) mandate that children be at least 6 months old to be anesthetized in a freestanding ambulatory surgery center.

More recent studies suggest that postoperative apnea using current anesthetic techniques is much less common than previously reported and recommend overnight observation for premature infants who are younger than 50 weeks PCA (instead of 60 weeks PCA that was the previous recommendation) in the absence of specific risk factors. Factors that were associated with a higher incidence of postoperative apnea include prior history of apnea, low gestational age, very low-birth-weight, low weight at time of surgery, and a complicated neonatal course.

### Down Syndrome

Children with Down syndrome may be at increased risk of atlantoaxial subluxation under anesthesia secondary to ligamentous laxity of the atlantoaxial joint. This predisposes these children to spinal cord injury with airway manipulation during direct laryngoscopy for

endotracheal intubation. The prevalence of atlantoaxial instability (AAI) in patients with Down syndrome is approximately 15%, and an atlantoaxial distance interval of greater than 4 to 5 mm in any lateral view is abnormal. However, the radiographic evaluation of the cervical spine is not accurate before 3 years of age because of inadequate vertebral mineralization and epiphyseal development.

The American Academy of Pediatrics guidelines for health supervision of children with Down syndrome (2011) do not recommend routine cervical spine radiographs for asymptomatic children. The usefulness of lateral cervical radiographs in asymptomatic children is controversial at best. A thorough history and physical examination should be done to search for any signs and symptoms of cervical spine instability. Neurologic manifestations of AAI include neck pain, limited neck mobility, torticollis, numbness and tingling or weakness in an extremity, difficulty walking, gait abnormalities, sensory deficits, spasticity, hyperreflexia, clonus, and bowel or bladder dysfunction. There should be a high index of suspicion for AAI in a child with Down syndrome who presents with deterioration in motor skills, torticollis, or new-onset incontinence.

For the symptomatic child, plain cervical spine radiographs should be obtained in the neutral position. If these show significant abnormalities, no further radiographs should be taken and prompt neurosurgical referral is mandated.

If a child with Down syndrome has signs and symptoms indicative of cervical spine instability, or if the cervical spine radiograph displays an atlantodens interval of greater than 5 mm, elective surgery should be postponed and neurosurgical consultation sought.

Another important consideration for the child with Down syndrome in the perioperative period is the concomitant presence of CHD. Anomalies of the cardiovascular system occur in approximately 40% to 50% of children with Down syndrome. The 3 most commonly associated heart defects are complete atrioventricular canal, ventricular septal defect, and atrial septal defect. Children with Down syndrome should be screened for the presence of heart disease in early infancy. Heart failure may be heralded by tachypnea, feeding difficulties, and failure to thrive. An echocardiogram should be performed, and cardiology consultation should be obtained when appropriate. See Box 63-15 for anesthetic concerns in children with Down syndrome.

#### BOX 63-14 Anesthetic Concerns With Prematurity

##### PERIOPERATIVE CONCERNS

- Postoperative apnea
- Postoperative bradycardia
- Presence of other comorbidities
- Need for admission to hospital after procedure

##### PREDICTORS OF POSTOPERATIVE APNEA

- Low gestational age (<37 weeks premature birth)
- Anemia (<10 g/dL Hgb)
- Previous episodes of apnea
- Complicated neonatal course
- Low weight at time of surgery

#### BOX 63-15 Anesthetic Concerns in Children With Down Syndrome

- Airway: Macroglossia, subglottic stenosis
- Obstructive sleep apnea
- Atlantoaxial instability
- CHD
- Hypotonia
- Hypothyroidism
- GERD

**Table 63-4** Preoperative Considerations for Patients With Cancer**PHYSIOLOGIC EFFECTS OF TUMOR**

Mass effect (anterior mediastinal mass, airway compromise)  
 Tumor lysis syndrome (hyperkalemia, hyperphosphatemia, renal impairment, hypocalcemic seizures, metabolic acidosis, cardiac arrhythmia)  
 Altered hemostasis

Imaging studies (CT, MRI) needed  
 Hydration, correction of acidosis and electrolyte imbalance before elective procedures

Check CBC, increased bleeding risk

**EFFECTS OF CHEMOTHERAPEUTIC AGENTS**

Bone marrow suppression

Anemia

Neutropenia

Thrombocytopenia

Assess need for perioperative blood transfusion  
 Immunocompromised state, increased infection risk, need for protective isolation, perioperative antibiotics  
 Assess need for platelet transfusion, regional anesthesia may be contraindicated  
 Obtain baseline and serial echocardiograms  
 Concern for hypoxia, chest radiograph

Cardiotoxicity

Pulmonary toxicity

Nephrotoxicity

Neurotoxicity

**EFFECTS OF RADIATION THERAPY**

Radiation therapy to the neck or oral cavity can render the airway difficult

**PRESENCE OF CHRONIC PAIN SYNDROMES AND ANALGESIC REQUIREMENT**

Important to determine accurate doses of opioids and other medications used for neuropathic pain

Important to continue opioid analgesics and other medications (antidepressants, anticonvulsants) in the perioperative period to prevent withdrawal

**PSYCHOLOGICAL ISSUES**

Depression, anxiety

Pharmacotherapy, counseling, support groups

Derived from Latham GJ, Greenberg RS. Anesthetic considerations for the pediatric oncology patient—part 1: a review of antitumor therapy. *Paediatr Anaesth.* 2010;20(4):295–304; Latham GJ, Greenberg RS. Anesthetic considerations for the pediatric oncology patient—part 2: systems-based approach to anesthesia. *Paediatr Anaesth.* 2010;20(5):396–420; Haberkern CM, Webel NE, Eisses MJ, Bender MA. Essentials of hematology. In: Cote CJ, Lerman J, Todres ID, eds. *A Practice of Anesthesia for Infants and Children.* 4th ed. Philadelphia, PA: Saunders Elsevier; 2009:191–194.

PCPs can help in the preoperative assessment by:

- Obtaining radiographs of the cervical spine when indicated
- Obtaining echocardiogram and cardiology consultation before a scheduled elective procedure in relevant cases
- Communicating all pertinent findings to the anesthesiologist

**Oncologic Disease**

Children with cancer typically require multiple anesthetics for different procedures, including diagnostic procedures (MRIs, CT scans), major operations for tumor resection, and minor procedures (eg, for central venous access (infusaport placements), radiation therapy, bone marrow biopsies, lumbar punctures).

The anesthetic care of patients with cancer can be particularly challenging and requires a thorough understanding of the physiologic effects of the various childhood tumors, toxicities of chemotherapeutic agents, and systemic effects of radiation treatment. Anesthetic concerns for cancer patients (outlined in Table 63-4) can be categorized as follows:

- Physiologic effects of the tumor
- Toxicities of various chemotherapeutic agents (see Table 63-5)
- Effects of radiation therapy
- Drug interactions between chemotherapy medications and anesthetic agents

- Presence of chronic pain syndromes
- Psychological issues

The preoperative preparation of patients with cancer should take into account both patient factors (eg, type of tumor, complications of therapy) and the complexity of procedure (major surgery versus a minor procedure such as a lumbar puncture). For instance, if a child with cancer is anemic from myelosuppression secondary to chemotherapy, it may be fine to proceed with the anesthetic for a diagnostic procedure (MRI, CT, lumbar puncture, bone marrow biopsy). However, for the same child it may be prudent to plan a preoperative transfusion before a major surgical procedure that can involve blood loss.

Ideally, a multidisciplinary approach involving coordination between the PCP, the pediatric oncologist, the surgeon, and the anesthesiologist should be adopted to ensure the best possible outcome for the patient.

**Endocrine Disease****Hypothyroidism**

The preoperative diagnosis and optimization of patients with hypothyroidism is essential for the provision of safe anesthetic care (see Box 63-16). Untreated hypothyroidism can predispose a patient to serious anesthetic complications, including coma and cardiorespiratory collapse.

**Table 63-5** Adverse Effects of Commonly Used Chemotherapeutic Agents

CHEMOTHERAPEUTIC AGENT	TOXICITY	ANESTHETIC IMPLICATIONS
Bleomycin	Pulmonary fibrosis	Important to elicit history of bleomycin use Obtain chest radiograph in high-risk patients Check room air oxygen saturation Avoidance of high FiO <sub>2</sub> concentration and fluid restriction in the perioperative period
Busulfan	Pulmonary toxicity Hepatotoxicity	
Corticosteroids	Adrenal suppression, hypertension, obesity, hyperglycemia	Need for stress dose steroids perioperatively
Cisplatin	Nephrotoxicity	Check electrolytes
Doxorubicin Daunorubicin	Peripheral neuropathy Cardiomyopathy	Document pre-existing neurologic deficits Baseline echocardiogram before initiating therapy and monitor serial echocardiograms Cardiac consultation in high-risk patients Avoid cardiodepressant drugs
Methotrexate	Myelosuppression Mucositis	Check complete blood count Increased risk of aspiration and airway compromise with mucositis
6-Mercaptopurine (6-MP)	Hepatotoxicity Mucositis	
Vinblastine Vincristine	Hepatotoxicity Neurotoxicity, peripheral neuropathies SIADH	Document existing sensorimotor deficits to distinguish between neuropathies from positioning and complications of regional anesthesia

Derived from Haberkern CM, Webel NE, Eisses MJ, Bender MA. Essentials of hematology. In: Cote CJ, Lerman J, Todres ID, eds. *A Practice of Anesthesia for Infants and Children*. 4th ed. Philadelphia, PA: Saunders Elsevier; 2009:191–192; Maxwell LG, Goodwin SR, Mancuso TJ, et al. Systemic disorders. ### BOX 63-16 Anesthetic Concerns in Children With Hypothyroidism

- Cardiac: Bradycardia, myocardial depression, hypotension, torsades de pointes
- Sleep apnea: increased sensitivity to sedatives and narcotics
- Blunted ventilatory response to hypoxia and hypercarbia
- Respiratory muscle weakness
- Airway obstruction resulting from macroglossia and obesity
- Increased sensitivity to anesthetic agents
- Slow drug metabolism (prolonged effects of anesthetic agents)
- Hypothermia
- Resistance to catecholamines

### Hyperthyroidism

Anesthetic concerns in children with hyperthyroidism are summarized in Box 63-17.

Thyroid storm is a hypermetabolic state manifested by hypertension, tachycardia, arrhythmias, and hyperthermia. Differential diagnosis includes malignant hyperthermia and pheochromocytoma.

The primary objective for the child with thyroid disease (hypo- or hyperthyroidism) is for the child to be clinically euthyroid. Children who are euthyroid are generally at no increased perioperative risk.

### BOX 63-17 Anesthetic Concerns in Children With Hyperthyroidism

- Arrhythmias
- Atrial fibrillation
- Hypertension
- Angina, ischemia
- High output cardiac failure
- Exaggerated response to catecholamines
- Thyroid storm
- Goiter (may cause airway compromise)

Children with thyroid disease should have a recent evaluation of thyroid-stimulating hormone and free T<sub>4</sub> levels. In the case of clinical evidence of thyroid disease or abnormal laboratory values, elective surgery should be postponed until a euthyroid state is achieved. This can be done in conjunction with a pediatric endocrinologist. If patients have any cardiac symptoms or if there is any indication of an arrhythmia on physical examination, an ECG should be performed to look for atrial fibrillation, ischemia, or ventricular hypertrophy. Furthermore, any child with a goiter should have radiologic evaluation of the airway; usually a CT scan or MRI is indicated to determine the extent of airway involvement. A large retrosternal goiter or airway involvement can have profound anesthetic implications and significantly alter the anesthetic plan.

**Table 63-6****Anesthetic Concerns in Children With Diabetes Mellitus****DELETERIOUS EFFECTS OF HYPERGLYCEMIA**

Delayed wound healing	Increased infection risk
Impaired phagocyte function	
Hyperosmolarity	Osmotic diuresis leading to Ketosis

Acidosis  
Electrolyte imbalance

**HYPOGLYCEMIA**

Altered mental status	Central nervous system damage
-----------------------	-------------------------------

Tachyarrhythmias  
Hemodynamic instability

**DIABETIC STIFF JOINT SYNDROME**

Immobility of the atlantoaxial joint	Potentially difficult intubation
--------------------------------------	----------------------------------

**AUTONOMIC NEUROPATHY**

Gastroparesis	Increased aspiration risk
Peripheral neuropathy	Documentation of existing deficits prior to performing regional anesthesia

Silent myocardial infarction

Derived from Copeland KC, Silverstein J, Moore KR, et al. Management of newly diagnosed type 2 Diabetes Mellitus (T2DM) in children and adolescents. *Pediatrics*. 2013;131:364–382; Butterworth JF IV, Mackey DC, Wasnick JD. Anesthesia for patients with endocrine disease. In: Butterworth J, Mackey DC, Wasnick J. *Morgan & Mikhail's Clinical Anesthesiology*. 5th ed. Blacklick, OH: McGraw-Hill Education; 2013:730–731; Specthrie LK, Reed AP. Case 29: diabetes mellitus. In: Reed AP, Yudkowitz FS, eds. *Clinical Cases in Anesthesia*. 3rd ed. Philadelphia, PA: Saunders Elsevier; 2005: 149–154; Salzarulo HH, Taylor LA. Diabetic “stiff joint syndrome” as a cause of difficult endotracheal intubation. *Anesthesiology*. 1986;64(3): 366–368.

**Diabetes Mellitus**

Diabetes mellitus is the most common endocrine disorder in children. It is a metabolic disorder characterized by hyperglycemia secondary to relative insulin deficiency or resistance, or both. The incidence of type 1 diabetes or IDDM has been steady at 5% to 15% in the United States, whereas the incidence of type 2 diabetes or NIDDM has been rising; this has been linked to the increasing obesity rates. See Table 63-6 for anesthetic concerns in children with diabetes mellitus.

Parents and patients should be involved in the planning process. Preoperative assessment and preparation should entail:

- Accurate documentation of pharmacologic regimen (medication type: insulin, oral hypoglycemic agent, dosage, timing)
- Maintaining good glycemic control
- Monitoring and recording the occurrence of hypoglycemic episodes (frequency, severity)

Furthermore, preoperative evaluation of the child with diabetes should also focus on the long-term complications of diabetes. These can be broadly categorized as shown in Box 63-18.

**BOX 63-18 Long Term Complications of Diabetes****MACROVASCULAR COMPLICATIONS**

- Stroke
- Myocardial infarction
- Peripheral vascular disease

**MICROVASCULAR COMPLICATIONS**

- Retinopathy
- Nephropathy
- Autonomic and somatic neuropathy

Laboratory investigations for the diabetic child include blood glucose, urea, creatinine, and electrolytes. Urine analysis should be performed to look for ketonuria. HbA1C measurement is not routinely performed; however, it is a good indicator of long-term glycemic control.

The goals of perioperative management are to avoid hyperglycemia and hypoglycemia. Traditionally, the perioperative target for serum glucose was 120 to 200 mg/dL. However, multiple adult studies have demonstrated that hyperglycemia is an important factor that contributes to increased perioperative morbidity and mortality, and that stringent glycemic control improves perioperative outcomes. A pediatric study by Pham et al (2005) analyzed the effect of tight glycemic control in severely burned children. They established that intensive insulin therapy to maintain normoglycemia was associated with decreased infection rates and improved survival. These recent studies recommend tighter glycemic control (80 to 110 mg/dL), and several protocols for tight glycemic control are emerging.

The disadvantage of maintaining tight glycemic control is the risk for developing hypoglycemia. Close monitoring of serum glucose levels is therefore required.

The general principles for the perioperative management of the patient with diabetes are as follows:

- All efforts should be made to schedule patients with diabetes as the first cases of the day to minimize the fasting period and to minimize disruptions in the treatment regimen.
- Children should have their blood glucose checked on arrival to the hospital the morning of surgery. Ideally, blood glucose level should be lower than 200 mg/dL and elective surgery should be postponed for levels higher than 300 mg/dL.
- Oral hypoglycemic agents are discontinued preoperatively. Metformin should be stopped 48 hrs before surgery because of its potential to cause lactic acidosis. These children can be treated with short-acting insulin preparations given subcutaneously, or a sliding-scale insulin protocol can be started to prevent hyperglycemia.
- Insulin is generally continued in the perioperative period. Typically, the morning dose of insulin is halved on the day of surgery or a sliding-scale

**Table 63-7** Multisystem Effects of Sickle Cell Disease

Hematologic	Hemolytic anemia
Respiratory	Acute chest syndrome: cough, dyspnea, hemoptysis, pleuritic chest pain
Cardiovascular	High-output cardiac failure secondary to anemia, cardiomegaly
Neurological	Increased risk of stroke/CVA
Renal	Renal concentrating defect, hematuria, renal insufficiency
Liver	Chronic hemolysis: jaundice and gallstones
	Frequent blood transfusions: hemosiderosis
Skeletal	Shortening of limbs, gross deformity of joints, osteomyelitis
Dermatologic	Skin ulcers (primarily leg ulcers)
Immunologic	Increased infection risk
Pain crisis	Vaso-occlusive pain crisis involving different sites
Psychological	Depression from chronic pain, chronicity of illness, multiple hospitalizations

Derived from Henderson K. Sickle cell disease and anaesthesia. *Update in Anaesthesia*. 1994. Available at: [www.wfsahq.org/components/com\\_virtual\\_library/media/b3992d0cbf6512b8679cd284616b1235-Sickle-Cell-Disease-and-Anaesthesia--Update-4-1994-.pdf](http://www.wfsahq.org/components/com_virtual_library/media/b3992d0cbf6512b8679cd284616b1235-Sickle-Cell-Disease-and-Anaesthesia--Update-4-1994-.pdf) Accessed January 25, 2016.

insulin regimen is instituted along with an intravenous infusion of 5% dextrose. However, checking the serum glucose level is mandatory and guides management.

- Increasingly, children with IDDM are managed with insulin pumps. Communication between the anesthesiologist and the endocrinologist regarding the perioperative management of insulin pumps may be necessary.
- Blood glucose is checked at regular intervals during the surgery and continued during the postoperative period. A good strategy for improving outcomes is the achievement of tight glycemic control preoperatively and then maintaining the same during surgery and the remainder of the hospital course. A collaborative plan can be devised by the PCP, pediatric endocrinologist, anesthesia physician, and surgeon.

### Sickle Cell Disease

Sickle cell disease is a hemoglobinopathy that is inherited in an autosomal recessive manner. Hemoglobin A (Hb A) constitutes 97% of the normal adult hemoglobin; it comprises 2  $\alpha$  chains and 2  $\beta$  chains. Sickle cell disease results from a single amino acid substitution (valine for glutamic acid) at the sixth position of the  $\beta$  globin chain. Those who are heterozygous for this condition (Hb AS) have sickle cell trait whereas those who are homozygous (Hb SS) have sickle cell disease. The structurally abnormal Hb, *Hb S*, is unstable and polymerizes when deoxygenated, causing the red blood cells to *sickle*. Sickling leads to:

- RBC hemolysis, which leads to anemia
  - Impaired passage of cells through the microcirculation, leading to small vessel obstruction and tissue damage. This causes recurrent episodes of vaso-occlusion and severe pain.
  - Progressive end organ damage
- Sickle cell disease is characterized by progressive end organ dysfunction. Pulmonary and neurologic complications are the leading cause of morbidity and mortality. The table and boxes that follow list the multisystem effects of sickle cell disease (Table 63-7), factors precipitating sickling (Box 63-19), goals for perioperative management (Box 63-20), high-risk patients with

### BOX 63-19 Factors Precipitating Sickling

- Hypoxia
- Infection
- Dehydration
- Acidosis
- Hypothermia

sickle cell disease (Box 63-21), and the investigations needed for these high-risk patients (Box 63-22).

### Mitochondrial Myopathies

Commonly encountered mitochondrial syndromes in the perioperative setting include:

- Leigh disease
- Kearns-Sayre syndrome
- Leber hereditary optic neuropathy

The genetics of mitochondrial myopathies is complex. Mitochondria are inherited from the mother. However, there is variable expression of the disease, because different populations of the mitochondria are transmitted to the offspring. Mitochondria are the major source of energy metabolism in the cell. The muscles and nerve tissue are particularly dependent on mitochondria for energy. The process of oxidative phosphorylation within the mitochondria is the major source of ATP. Conditions that cause the depletion of ATP stores lead to cell breakdown and acidosis. Affected patients are at increased risk of metabolic decompensation, especially during times of increased stress.

The clinical features of mitochondrial diseases include myopathy, cardiomyopathy, encephalopathy, seizures, cerebellar ataxia, and GI symptoms. The preoperative assessment of patients with mitochondrial diseases should entail a thorough assessment of cardiac and respiratory function and the measurement of baseline lactate, electrolytes, and creatine kinase (CK) levels. Increased serum and cerebrospinal fluid lactate and pyruvate levels are seen in these patients. Box 63-23

**BOX 63-20 Objectives in the Perioperative Period**

- Thorough assessment of the patient to identify the presence of multisystem involvement:
  - History of acute chest syndrome
  - History of vaso-occlusive pain crisis, hospitalizations
  - Neurologic assessment (hemiparesis, cognitive impairment)
  - History of chronic analgesic use and requirement
  - History of hematuria, renal insufficiency
- Optimization of cardiopulmonary status:
  - Treatment of acute chest syndrome: hydration, supportive treatment, supplemental oxygen, aggressive bronchodilator therapy, antibiotics, chest physiotherapy, incentive spirometry, and often transfusion.
  - Hydroxyurea therapy and chronic transfusion therapy: these have been shown to decrease the frequency of acute chest syndrome episodes. Inhaled nitric oxide (NO) has been proved to be beneficial for acute management.
- Correction of anemia:
  - The National Institute of Health in their 2002 publication on the management of sickle cell disease recommend: "In patients with SCD-SS, simple transfusion to achieve a hemoglobin of 10 g/dL should be performed before all but the lowest risk procedures."<sup>a</sup>
  - Very high-risk patients may require a more aggressive transfusion approach. Cerebrovascular disease occurs in approximately 8% of patients with SCD. Transfusion programs aimed at maintaining HbSS level below 30% reduce the risk of recurrent stroke from 60%–70% to less than 10%.<sup>b</sup> Children at high risk for cerebrovascular accidents (as identified by abnormalities on MRI and transcranial Doppler exams) are usually maintained on chronic intermittent transfusions, and this regimen should be continued in the perioperative period.
- Prevention of vaso-occlusive crisis:
  - Prolonged fasting should be avoided to prevent dehydration and subsequent vascular stasis that can promote sickling.
  - Ideally, these patients should be admitted before surgery and intravenous hydration should be initiated during the fasting period.
  - Optimize analgesia: a strategy for pain control should be devised, and pediatric pain service (if available) should be involved early in the care of these patients, especially those with frequent pain crisis.
- Any ongoing infections should be treated before elective procedures.

lists the anesthetic considerations for patients with mitochondrial myopathies.

## IMPORTANCE OF MULTIDISCIPLINARY APPROACH

At present, the delivery of health care services is fragmented. There is a need to transition to an integrated model with coordination of patient care services. Information regarding the child's history may be scattered. An important role of the PCP is the compilation of the medical record so that the information is easily available to the child's caregivers on the day of surgery. Also, the communication of abnormal findings, laboratory results, and recommendations of specialists to other health care personnel (anesthesiologists, surgeons) is crucial. A collaborative effort is required to attain improved patient outcomes.

## CONTINUOUS QUALITY IMPROVEMENT MEASURES

Quality and process improvement efforts aim to improve outcomes and promote efficiency and maximal use of resources with the added benefit of cutting costs.

The use of benchmarking systems pertaining to quality-of-care measures is needed. These will help identify and analyze problems in health care delivery. Once issues are recognized, solutions can be implemented. To

### BOX 63-23 Anesthetic Considerations in Children With Mitochondrial Myopathies

- **Respiratory muscle weakness:** Increased sensitivity to volatile anesthetics and narcotic medications predisposes to development of postoperative respiratory insufficiency.
- **Cardiomyopathy:** Warrants judicious use of agents that can further depress myocardial function. Preoperative assessment of cardiac function by echocardiogram is required, and cardiac consultation should be sought when required.
- **Cardiac conduction defects:** Baseline ECG should be obtained preoperatively, and drugs with arrhythmogenic potential should be avoided intraoperatively.
- **Avoid prolonged fasting,** which can lead to an exaggerated metabolic response, causing acidosis. Intravenous hydration with glucose-containing fluids should be initiated while the patient is NPO to avoid anaerobic metabolism. Avoidance of lactated ringer's solution to prevent additional lactate load is advisable.
- **Maintain normothermia:** Shivering secondary to hypothermia can have deleterious effects on already compromised cellular metabolism. Also, hyperthermia is undesirable.
- **Maintain hematocrit** near normal levels to ensure adequate oxygen delivery.
- **Avoid hypotension and hypoxia.**
- **Pain can increase sympathetic tone,** leading to increased oxygen demand, so appropriate pain management is necessary.

improve outcomes for the perioperative child, physicians can use:

- Patient satisfaction surveys
- Data collection and analysis for adverse perioperative events
- Data collection regarding surgery cancellations

### SUMMARY

A comprehensive preoperative evaluation not only entails the identification and management of a child's medical condition but also requires communication with other members of the health care team to formulate a perioperative care plan that best suits the child's needs. The evaluation is fundamental to minimizing the inherent risks of anesthesia and surgery and to improving outcomes. The PCP can contribute by understanding the effects of general anesthesia on physiologic processes and by having an appreciation of the anesthesiologist's concerns. Ideally, a multidisciplinary approach should be adopted to ensure the delivery of the best care and the most efficient use of resources.

## Chapter 64

## POSTOPERATIVE CARE

Jennifer Aunspaugh, MD; Jayant K. Deshpande, MD, MPH

### INTRODUCTION

During the past 25 years, outpatient (ambulatory) anesthesia and surgery have revolutionized the way surgery and anesthesia are practiced in North America. Safe, reliable, inexpensive, and convenient outpatient surgery is an attractive option for parents,

children, their physicians, and perhaps most importantly, their insurers. Surgical procedures that routinely required 1 or 2 days of preadmission hospitalization and 1 to 7 days of postoperative recuperation are now commonly performed without any inpatient hospitalization at all. The cost savings are substantial; the average cost of 1 day in an American hospital is approaching \$5,000 in some areas. Government and private health care insurers are demanding increased use of ambulatory surgery services and will pay for even fewer inpatient procedures. Besides cost savings, outpatient surgery has additional advantages. Ambulatory anesthesia and surgery reduce the psychological trauma of hospitalization and family separation, cause fewer nosocomial infections, and hasten recovery. Examples of surgical procedures that now are routinely performed in children on an outpatient basis are listed in Box 64-1.

### COMPLICATIONS

The incidence of serious postoperative complications in healthy children undergoing ambulatory surgery is relatively low. Common anesthetic and surgical postoperative problems can be classified into early and late, depending on the time of onset. In many instances, the family will call on the larger center hospitalist (general pediatrics), rather than the surgeon or anesthesiologist, to diagnose and treat these problems. The hospitalist must therefore be aware of the

existence of and recommended treatment for these complications.

### SELECTION OF PATIENTS

Guidelines for selecting appropriate procedures and patients for outpatient surgery and anesthesia are continually evolving and are discussed in greater detail in Chapter 63, Preoperative Assessment. In general, the procedure itself should not involve excessive bleeding or open entry into a major body cavity. Patients with comorbidities such as obesity, uncontrolled asthma, upper airway problems, central nervous system (CNS) dysfunction, technology dependence (eg, ventilator-dependent patients) should not be selected to receive anesthesia in a free-standing outpatient surgery center. Additionally, the patient should not require any special postoperative nursing care and must have a responsible adult at home who will be available to provide care until recovery is complete.

### EARLY POSTOPERATIVE ANESTHETIC PROBLEMS

The most frequent complications of general anesthesia are postoperative nausea and vomiting (PONV). These adverse effects are the most common cause of delayed discharge from the postanesthesia care unit (PACU, formerly called the recovery room) and unanticipated hospitalization after outpatient surgery. Risk factors associated with PONV are listed in Box 64-2.

Certain surgical procedures are associated with a greater than 50% incidence of postoperative vomiting. These are listed in Box 64-3.

#### BOX 64-1 Common Outpatient Surgical Procedures by Specialty

##### GENERAL SURGERY

- Incision and drainage of abscesses
- Femoral, inguinal, and umbilical herniorrhaphies
- Lymph node and other diagnostic biopsies
- Central line insertion
- Fistulotomy

##### GENITOURINARY SURGERY

- Orchiopexy, hydrocele
- Circumcision
- Hypospadias repair

##### OTORHINOLARYNGEAL SURGERY

- Myringotomy and tube placement
- Adenoidectomy
- Tonsillectomy
- Bronchoscopy

##### OPHTHALMOLOGIC SURGERY

- Strabismus
- Examination under anesthesia

##### ORTHOPEDIC SURGERY

- Tendon lengthening
- Spica changes
- Fracture reductions

#### BOX 64-2 Patient Risk Factors for Postoperative Nausea and Vomiting

- Female gender
- Obesity
- Age, with risk increasing as the child enters puberty
- Previous history of Postoperative Nausea and Vomiting or motion sickness
- Poorly controlled pain
- High levels of anxiety

#### BOX 64-3 Surgical Procedures Contributing to Postoperative Nausea and Vomiting

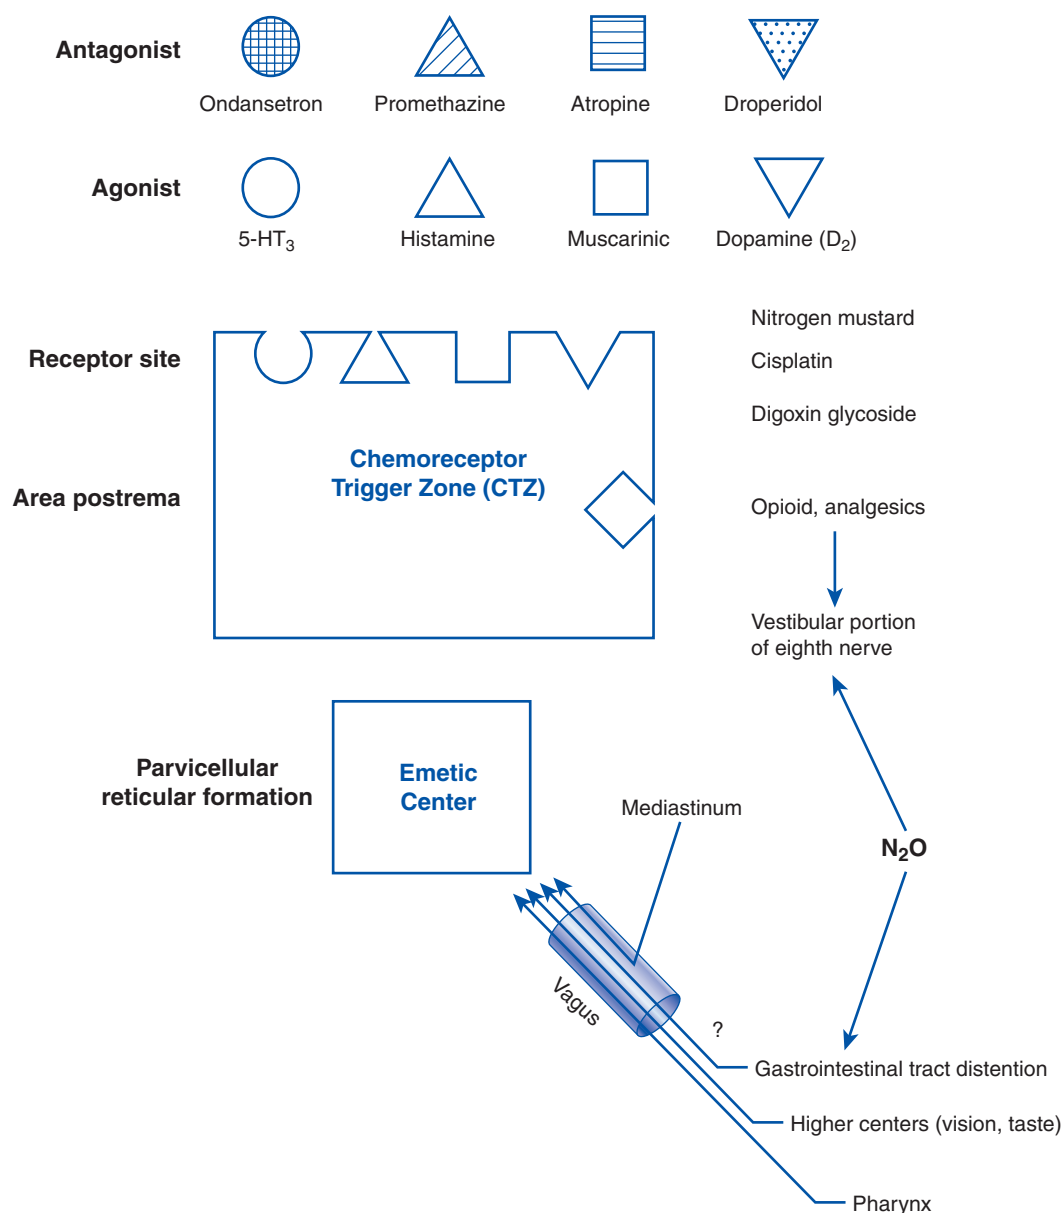

- Tonsillectomy and adenoidectomy
- Tympanoplasty or any middle ear surgery
- Strabismus repair
- Orchiopexy
- Inguinal or umbilical hernia repairs
- Penile surgery
- Major gynecologic surgery

The complex act of vomiting involves coordination of the respiratory, gastrointestinal, and abdominal musculature and is controlled by the emetic center. Stimuli from several areas within the CNS can affect the emetic center. These stimuli include afferents from the pharynx, gastrointestinal tract, and mediastinum, as well as afferents from the higher cortical centers (including the visual center and the vestibular portion of the eighth nerve) and the chemoreceptor trigger zone in the area postrema of the ventral lateral nucleus. The area postrema of the brain is rich in dopamine, opioid, and serotonin receptors. Therefore, blockade of these receptors is an important mechanism of action of the most commonly used antiemetics (Figure 64-1 and

Table 64-1). Several techniques are available to treat or prevent postoperative nausea and vomiting, including altering the anesthetic technique (eg, avoiding the perioperative use of opioids), providing adequate fluid hydration with isotonic solutions intraoperatively, administering antiemetics perioperatively either prophylactically or as treatment (eg, droperidol, phenothiazines, ondansetron, or antihistamines; Table 64-2), and limiting oral intake postoperatively.

### Contribution of Anesthetic Technique to Postoperative Nausea and Vomiting

Certain anesthetic agents and techniques produce more vomiting than others. These are listed in Box 64-4.

**Figure 64-1** The chemoreceptor trigger zone and the emetic center with the agonist and antagonist sites of action of various anesthetic-related agents and stimuli. Derived from Altman DF. Drugs used in gastrointestinal diseases. In: Katzung BG, ed. *Basic and Clinical Pharmacology*. 8th ed. New York, NY: Lange Medical Books/McGraw-Hill; 2001.

Volatile anesthetics have repeatedly been shown to cause more PONV than intravenous (IV) anesthetic techniques; however, of all of the volatile agents, desflurane has been touted to be associated with less PONV than previous agents. An IV general anesthetic agent, propofol, produces significantly less vomiting and nausea than others, if opioids are not given concomitantly. Indeed, opioids, including morphine, meperidine, fentanyl, codeine, oxycodone, and hydromorphone, have been consistently shown to cause nausea and vomiting. Individual patients may find one opioid drug more nauseating than another; sometimes, changing from one drug to another may decrease the amount of nausea and vomiting. Finally, although regional anesthetic techniques that use local anesthetics either centrally (eg, epidural) or peripherally (peripheral nerve block) produce less vomiting than general anesthetic techniques, using these techniques is rarely possible without concomitant general anesthesia in children.

Avoiding opioids perioperatively may solve only part of the puzzle. Obviously, pain control is essential in children who undergo surgery, and opioids are the most common analgesic drugs used for this purpose (see Chapter 54, Managing Acute Pain in Children). An alternative may be ketorolac, a powerful nonsteroidal anti-inflammatory drug (NSAID), which is almost as potent as morphine as an analgesic but does not produce nausea, vomiting, or respiratory depression. Because NSAIDs affect platelet aggregation and adhesiveness, their use is limited in many patients who are at risk for postoperative bleeding, particularly children who have undergone tonsillectomy. In addition, many orthopedic surgeons forbid the use of NSAIDs during and after operations in which new bone formation is important (fractures, spine fusions)

because NSAIDs have been shown to impair osteoblastic activity. The extent to which this effect is clinically important is controversial. Another alternative to opioids in children is IV acetaminophen, which has just recently been released for clinical use by the US Food and Drug Administration (FDA) for children older than 2 years. Studies with IV acetaminophen have shown that it decreases the need for opioids significantly, therefore lowering the threshold for PONV.

### Contribution of Postoperative Oral Intake to Postoperative Nausea and Vomiting

Many anesthesiologists prefer to restrict patients from taking anything by mouth until they are ready and willing to drink and eat, even if this restriction means that the child leaves the hospital while still fasting. Basically, children must say that they are thirsty, or better still, hungry, and must specifically ask for something to drink or eat before any food or liquid is offered. Even in the youngest patients, the risk for dehydration is low, particularly if IV fluids were appropriately administered perioperatively. In current anesthetic practice, virtually all children undergoing surgery and anesthesia receive hypotonic electrolyte-containing solutions intravenously in the operating room and PACU. If fluids sufficient to supply maintenance and replacement requirements were given during this period, a postoperative fast will be readily tolerated. Thus, just as anesthesiologists are abandoning stringent, prolonged preoperative fasts, they are increasingly appreciating their benefits postoperatively. The studies that questioned mandatory oral fluids before discharge in pediatric patients revealed that neither drinking nor nondrinking worsened

**Table 64-2** Dosage Guidance for Commonly Used Antiemetics

PHARMACOLOGIC GROUP (GENERIC)	BRAND NAME	DOSAGE (mg/kg)	ADVERSE EFFECTS
<b>PHENOTHIAZINES</b>			
Chlorpromazine	Thorazine	IV, PO: 0.5–1.0 every 6–8 hr	Drowsiness, hypotension, arrhythmias, extrapyramidal symptoms; potentiates effects of opioids, sedatives
Prochlorperazine	Compazine	PO, PR: 0.1 every 6–8 hr (maximum dose, 10 mg)	
<b>BUTYROPHENONES</b>			
Droperidol	Inapsine	IV: 0.01–0.03 every 6–8 hr	Drowsiness, hypotension, arrhythmias; droperidol has black box warning: prolongs QT interval, extrapyramidal symptoms; lowers seizure threshold; potentiates effects of opioids, sedatives
Haloperidol	Haldol	IV: 0.01 every 8–12 hr	
<b>ANTIHISTAMINES</b>			
Promethazine	Phenergan	IV: 0.25–0.5 every 6 hr	Drowsiness, hypotension, arrhythmias; contraindicated in patients taking MAO inhibitors; Phenergan contraindicated in children <2 years old because of cases of fatal respiratory depression. <sup>a</sup> Constipation, restless legs, paresthesia, dry mouth, vertigo
Diphenhydramine	Benadryl	0.5–1.0 every 4–6 hr (maximum dose, 50 mg)	
<b>BENZAMIDES</b>			
Metoclopramide	Reglan	IV, PO: 0.05–0.1 every 6 hr	Adverse effects include extrapyramidal symptoms
<b>ANTICHOLINERGIC</b>			
Scopolamine	Hyoscine transdermal scopolamine	IV, PO: 0.005 every 4–6 hr; apply behind ear 4 hr before needed; lasts 72 hr	Adverse effects include dry mouth, blurred vision, fever, tachycardia, constipation, urinary retention, drowsiness, amnesia
<b>STEROIDS</b>			
Dexamethasone	Decadron	IV: 0.1–0.5 every 4–6 hr; most effective when given in conjunction with ondansetron	Adverse effects include hyperactivity and insomnia, but are rarely observed at this dose range
<b>ANTISEROTONIN</b>			
Ondansetron	Zofran, Zofran ODT	IV, PO: 0.15 every 8 hr, (maximum dose, 4 mg)	Adverse effects include bronchospasm, tachycardia, headaches, lightheadedness, may prolong QT interval

IV, intravenous; MAO, monoamine oxidase; ODT, oral dissolving tablet; PO, oral.

<sup>a</sup>FDA MedWatch, [www.fda.gov/Safety/MedWatch/default.htm](http://www.fda.gov/Safety/MedWatch/default.htm). Accessed October 21, 2015.

The chemoreceptor trigger zone and the emetic center with the agonist and antagonist sites of action of various anesthetic-related agents and stimuli.

postoperative nausea or vomiting or prolonged hospital stay. Therefore, drinking oral fluids should not be required before discharge. These changes have been incorporated in the American Society of Anesthesiologists practice guidelines for postanesthetic care. Mandating oral fluid intake before discharge should be done only for selected patients on a case-by-case basis. Unfortunately, many institutions continue to require that patients drink and ambulate before they can be discharged from the hospital or same-day care unit. This restriction almost certainly contributes to the incidence of unanticipated admission to the hospital after outpatient surgery because of vomiting.

### Treatment of Postoperative Nausea and Vomiting

The treatment of PONV is the same as that used for viral gastroenteritis. A cooling-off period of 2 to 4 hours is followed by sips of clear fluids that contain electrolytes (eg, oral rehydration solution, Pedialyte [see Chapter 353, Dehydration]). Each sip is separated by several minutes. Giving fluids or solids prematurely may aggravate the problem. Antiemetics can be used either prophylactically or to treat the problem once it develops. The most common antiemetics are those that block receptors within the vomiting center. Four major neurotransmitter systems play a role in mediating the emetic response: dopaminergic, histaminic,

### **BOX 64-4 Anesthetic Agents That Contribute to Postoperative Nausea and Vomiting**

- Volatile agents such as sevoflurane, isoflurane or desflurane
- Nitrous oxide
- Opioids—these drugs stimulate the chemoreceptor trigger zone in the brain for nausea and vomiting. It is possible that intravenous morphine produces more nausea and vomiting than intravenous hydro-morphone. In respect to oral opioid medications, codeine has been noted to produce more nausea and vomiting than oxycodone.

cholinergic, and serotonergic. Antiemetic drugs may act at more than 1 receptor, but they tend to have a more prominent action at 1 or 2 receptors.

Unfortunately, most of these antiemetic classes, with the exception of the serotonin antagonists, produce sedation, which can interfere with rapid return to baseline function and therefore hospital discharge. In addition, promethazine has been identified as a contributing cause in a significant number of deaths in children younger than 2 years to whom it had been administered for vomiting that occurred either in the postoperative period after hospital discharge or because of gastroenteritis. For this reason, in 2004, the FDA mandated a black box warning. The original warning seemed to apply only to brand-name suppository formulations; the warning was clarified in 2006 to make sure that both health care professionals and parents understood that the warning applies to all formulations.

Medications containing promethazine hydrochloride (HCl) should not be used for children less than 2 years of age because of the potential for fatal respiratory depression. This includes promethazine HCl in any form: syrup, suppository, tablet, or injectable. Cases of respiratory depression including fatalities have been reported with use of promethazine HCl in children less than 2 years of age. Caution should also be exercised when administering promethazine HCl in any form to pediatric patients 2 years of age and older.

This warning is especially germane in children after surgery because they may be receiving opioids for analgesia, which may cause respiratory depression.

In September of 2009, the FDA mandated an additional black box warning for promethazine hydrochloride:

Perivascular extravasation, unintentional intra-arterial injection and intraneuronal or perineuronal infiltration of the drug may result in irritation and tissue damage, including gangrene.

The black box warning will remind physicians that because of the risks of IV injection, the preferred route of administration is deep intramuscular injection and that subcutaneous injection is contraindicated.

This action is based on FDA analysis of postmarketing reports of severe tissue injury, including gangrene, requiring amputation following IV administration of promethazine as well as on FDA review of the current prescribing information for these products. The FDA has determined that the presentation, organization, and content of the prescribing information should be revised to more effectively communicate the risk for severe tissue injury following IV administration.

In addition to the black box warning, the FDA is requiring a revision to the *Dosage and Administration* section to increase the visibility and accessibility of specific recommendations for the maximal concentration (25 mg/mL) and rate of administration (25 mg/min) when IV administration of promethazine is required.

As a result of this most recent black box warning, many pediatric institutions have removed IV promethazine from their formulary or have written specific protocols to follow when administering IV promethazine.

On December 5, 2001, the FDA issued a new black box warning on droperidol, a popular antiemetic for the treatment or prevention of PONV. Droperidol previously carried a warning regarding the potential for sudden cardiac death at high doses (>25 mg) in psychiatric patients. The revised warning suggests that even low doses of droperidol should be used only when other first-line drugs fail.

### **Pharmacology of Commonly Used Antiemetic Drugs**

Site of action, dose, and route of administration of the most commonly used antiemetics are listed in Table 64-1, Table 64-2, and Table 64-3. A new dose form of ondansetron, the oral dissolving tablet, has been found to be an effective and acceptable formulation in children undergoing adenotonsillectomy, as well as in infants and children with gastroenteritis treated in an emergency department. This drug, as with all serotonin antagonists, is slightly more expensive than older antiemetics, but it has the advantage of oral dosing and lack of side effects such as sedation and the extrapyramidal reactions seen with metoclopramide. The effective dose and therefore cost of serotonin antagonists can be reduced by the coadministration of IV dexamethasone in the perioperative period, which has also been shown to prolong the duration of the antiemetic effect of these drugs.

### **Prolonged Nausea and Vomiting**

Nausea and vomiting that persists beyond 12 to 24 hours is unusual and requires evaluation to determine the state of hydration and possible necessity of IV rehydration and to rule out alternative conditions. In rare instances, excessive air swallowing in the postoperative period may lead to acute gastric dilation in young children. Recognition of the characteristic distended abdomen, if present, should be followed by nasogastric decompression.

### **Effect of Postoperative Vomiting on Concomitant Medications**

Postoperative vomiting may interfere with the resumption of long-term oral medication regimens. With few exceptions (monoamine oxidase inhibitors,

**Table 64-3** Most Commonly Used Antiemetics in Order of Use

CLASS	DRUG AND COST PER DOSE
Serotonin antagonists: first choice	Ondansetron (\$0.58/4 mg), dolasetron (\$18.74/12.5 mg)
Steroids	Dexamethasone (\$0.99/4 mg) (most effective if given in conjunction with a serotonin antagonist and has been shown to extend the period of effective treatment up to 24 hrs)
Benzamides	Metoclopramide (\$0.88/10 mg), trimethobenzamide hydrochloride (\$15.03/100 mg)
Phenothiazines	Prochlorperazine (\$3.60/10 mg), promethazine (\$1.18/25 mg)
Butyrophenones	Droperidol (\$4.08/5 mg), haloperidol (\$7.49/5 mg)
Anticholinergics	Scopolamine (\$5.63/0.4 mg), atropine (\$0.96/0.4 mg)

**Table 64-4** Harmful Effects of Undertreated Severe Acute Pain

SYSTEM	EFFECTS
Respiratory	Decreased lung volumes, cough, atelectasis
Cardiovascular	Tachycardia, hypertension, increased myocardial oxygen consumption
Gastrointestinal	Decreased gastric and bowel motility
Genitourinary	Urinary retention
Endocrine	Vagal inhibition, increased adrenergic activity, increased metabolism and oxygen consumption
Central Nervous System	Anxiety, fear, fatigue
Immunologic	Infection, delayed wound healing

oral hypoglycemics, and diuretics), all long-term administered oral medications should be taken on the morning of surgery. Indeed, the question of whether patients should take oral medications on the morning of surgery has become moot because of the liberalization of preoperative fasting guidelines. This ability of patients to take their medications preoperatively has greatly reduced the stress associated with deciding when the use of oral medications can be restarted postoperatively. Most drugs administered in the long term, such as anticonvulsants, bronchodilators, and digitalis, have half-lives of elimination that are long (>12 hr), which means that missing a dose of these drugs for 1 or 2 half-lives (12–24 hr) will have minimal, if any, effect on blood levels. Of course, this situation assumes that therapeutic blood levels existed before surgery began. If vomiting persists beyond 24 hours, then parenteral drug administration may be required.

## POSTOPERATIVE PAIN MANAGEMENT

The treatment and alleviation of pain is fundamental to medical care, and a pain score has been added to clinical assessment as the fifth vital sign. The physician's obligation to manage pain and relieve patient suffering is a crucial element of the professional commitment to patient care. This concept is not merely a lofty ideal; effective pain management produces myriad patient benefits, including reduced morbidity and mortality, early mobilization, and more rapid recovery and return to work, school, and play (see Table 64-4 and Box 64-5.) (A detailed discussion of pain management can be found in Chapter 54, Managing Acute Pain in Children.)

### BOX 64-5 Benefits of Effective Pain Control

- Reduced morbidity and mortality
- Early mobilization
- More rapid recovery
- Rapid return to work
- Rapid return to school and play

## EMERGENCE PHENOMENA AFTER GENERAL ANESTHESIA

Emergence from general anesthesia in healthy patients is often accompanied by transient symmetrical neurologic changes that, under other circumstances, are considered pathologic reflexes. These otherwise pathologic reflexes include sustained and nonsustained ankle clonus, bilateral hyperreflexia, the Babinski reflex, and decerebrate posturing. These reflexes can often be detected within minutes of discontinuing a general anesthetic and may persist for hours, the reason for which is unknown. However, the discovery of focal neurologic deficits in a postoperative patient is never normal. Such neurologic deficits should point to a possible central or peripheral nervous system injury and requires investigation.

Children are prone to disorientation, hallucinations, and, at times, uncontrollable physical activity during emergence from general anesthesia. This hyperexcitable, hyperactive state is sometimes referred

**BOX 64-6 Causes of Emergence Delirium**

- Patient awakens in pain after receiving a vapor anesthetic (eg, sevoflurane, isoflurane, desflurane)
- Patient receives a vapor anesthetic such as sevoflurane independent of any painful stimulus (eg, for magnetic resonance imaging or computed tomography)
- Sensory deprivation (eye bandages or eye lubricant)
- Residual anesthetic
- Awakening in a strange environment (postanesthesia care unit) without parents
- Perioperative use of ketamine
- High level of anxiety preoperatively

Derived from Davis PJ, Greenberg JA, Gendelman M, Fertal K. Recovery characteristics of sevoflurane and halothane in preschool-aged children undergoing bilateral myringotomy and pressure equalization tube insertion. *Anesth Analg*. 1999;88(1):34–38; White PF, Way WL, Trevor AJ. Ketamine—its pharmacology and therapeutic uses. *Anesthesiology*. 1982;56(2):119–136.

**BOX 64-7 Characteristics of Emergence Delirium**

- Thrashing
- Disorientation
- Crying
- Screaming
- Inability to recognize parents or surroundings
- Inconsolability
- Talking irrationally during early emergence from anesthesia

**BOX 64-8 Treatments for Emergence Delirium**

- Small doses of analgesics (eg, fentanyl)
- Flumazenil, if midazolam was administered
- Small doses of dexmedetomidine

to as *emergence delirium* (Box 64-6 and Box 64-7) or *agitation*. Regardless of cause, before discharge from the PACU, most of the disorientation, hyperactivity, excitability, and hallucinatory visual disturbances should be completely resolved (Box 64-8).

Some anesthesiologists may use atropine during induction to counteract the bradycardia seen with succinylcholine in children. Therefore, atropine may be responsible for the characteristics of emergence delirium, in which case it will be accompanied by other features of anticholinergic syndrome (flushed cheeks, mydriasis, and low-grade fever). This reaction may be treated by administration of physostigmine, an anticholinesterase that crosses the blood-brain barrier and reverses the CNS effects of atropine by

**BOX 64-9 New-Onset Postoperative Maladaptive Behaviors**

- Sleep disturbances
- Nightmares (terrors)
- Separation anxiety
- Aggression toward authority
- Loss of nighttime bladder control on the night after surgery
- General anxiety

Derived from Kain ZN, Caramico LA, Mayes LC, et al. Preoperative preparation programs in children: a comparative examination. *Anesth Analg*. 1998;87(6):1249–1255.

potentiating the action of acetylcholine at nerve terminals. However, as a cautionary note, physostigmine has potential for severe side effects and/or risks to the patient if not used by providers who are experienced with this drug. Consultation with an experienced physician is recommended when considering the use of physostigmine. The prevalence of such anticholinergic reactions has been reduced since the replacement of halothane with sevoflurane as the primary gas for mask anesthetic induction in children. Sevoflurane does not cause the bradycardia seen with halothane, making routine use of atropine unnecessary in pediatric anesthetic practice, except when used to counteract the muscarinic effects of anticholinesterase administration for reversal of nondepolarizing muscle relaxant.

Occasionally, some lingering evidence of these behavioral perturbations may persist for 12 to 24 hours. Indeed, children who are extremely anxious before surgery and during the induction of anesthesia are more at risk for developing postoperative negative behavioral changes (Box 64-9) compared with children who seem calm before surgery and during the induction process. Anxious children would benefit from premedication with a benzodiazepine (midazolam) before the induction of anesthesia. Kain and colleagues have clearly demonstrated that oral premedication with midazolam is more effective than either parental presence or extensive preoperative behavioral programs at reducing preoperative anxiety and postoperative delayed alterations in behavior.

Ketamine, in particular, is associated with sleep disturbances after its administration. Although the incidence of nightmares after ketamine administration is lower in children than adults, it has been reported to occur in 5% to 10% of patients who receive it. However, the incidence is mitigated by the concomitant administration of benzodiazepine, usually midazolam. Fortunately, regardless of the cause, sleep disturbance is time limited and rarely persists beyond 48 hours after surgery and general anesthesia. If sleep disturbances become overwhelming, they can then be treated with oral diazepam. In most cases, 1 dose given at bedtime cures the problem completely.

Kain and colleagues state that reducing parental anxiety is an important factor in reducing these

### BOX 64-10 Characteristics of Children at High Risk for Developing Postoperative Maladaptive Behaviors

- Younger children
- Emotional children
- Impulsive children
- Less social children

The parents of these children are significantly more anxious in the waiting area and on separation to the operating room. Derived from Kain ZN, Caramico LA, Mayes LC, et al. Preoperative preparation programs in children: a comparative examination. *Anesth Analg*. 1998;87(6):1249–1255.

postoperative clinical phenomena and preoperative preparation programs directed at parents should be considered (Box 64-10).

## INTUBATION-RELATED COMPLICATIONS

On emerging from a general anesthetic, many children who have been endotracheally intubated or who have experienced either airway manipulation or instrumentation (laryngeal mask airway) will complain of a sore throat. This discomfort can be alleviated with fruit-flavored ice pops, ice chips, or common throat lozenges or sprays once cough, gag, and swallowing reflexes have returned to baseline. Analgesics are rarely required, but if they are, then acetaminophen will usually suffice.

## POSTEXTUBATION STRIDOR

Postextubation stridor, or postextubation subglottic edema, has been a well-recognized entity since airways were first secured by intubation. Children are more prone to develop croup after intubation than are adults because of differences in their airway anatomy. Children have narrower laryngeal and tracheal lumens that are more easily compromised by mucosal edema. Additionally, the narrowest portion of the younger child's airway is at the level of cricoid cartilage and not at the level of the larynx. Given that an endotracheal tube can easily pass through the vocal cords and become wedged in the subglottic area, internal tracheal mucosal injury can occur. Other contributing factors to the development of postextubation stridor are pre-existing subglottic stenosis or airway reconstructions, traumatic or repeated intubations, coughing (*bucking*) on the tube, changing the patient's position after intubation, and providing general anesthesia to children who have a current or recent upper respiratory tract infection.

The incidence of postintubation croup has decreased from 6% to 1% of all endotracheally intubated children. This reduction has occurred through the use of sterile, implant-tested endotracheal tubes and the routine intraoperative use of humidification of the administered gases and, in children younger than 5 years, by using appropriately sized (air leak pressure

<30 cm of water), uncuffed endotracheal tubes. Children who have Down syndrome may be at increased risk for this complication because of the increased incidence of occult subglottic narrowing.

The treatment of postintubation croup is similar to treatment of viral laryngotracheitis. Humidification of inhaled air is effective in most cases. In rare cases, positive pressure (noninvasive or invasive) or heliox may be required. Nebulized racemic epinephrine therapy is rarely necessary. If it is, then these patients should not be discharged from the PACU to their homes. Rather, they should be admitted for several hours of observation because of the potential for rebound edema formation. The efficacy of corticosteroids in treating postintubation croup has been controversial, although most studies have shown it to be effective. Most anesthesiologists will prescribe dexamethasone for this problem, even though no controlled, prospective trials have validated its use for this purpose.

## SUCCINYLCHOLINE-INDUCED MYALGIA

In the past, many anesthesiologists commonly used succinylcholine, a short-acting, depolarizing muscle relaxant, to facilitate intubation of the trachea in children. Because of the risk for fatal hyperkalemia in children with undiagnosed Duchenne muscular dystrophy when succinylcholine is administered, it is used less frequently. The use of succinylcholine by anesthesiologists caring for children has declined in favor of relatively fast-onset, nondepolarizing muscle relaxants such as rocuronium. Use of succinylcholine is now reserved for patients who have no known risk for malignant hyperthermia or hyperkalemia and who need true rapid-sequence intubation because of intestinal obstruction or increased gastric contents from a recent meal. Succinylcholine administration in all children normally will result in some damage to the muscle cell, with leakage of intracellular potassium. Some degree of myalgia and increased blood levels of creatinine phosphokinase and myoglobin are expected complications of succinylcholine administration. To some degree, the magnitude of these perturbations can be avoided by pretreating the patient with small doses of a nondepolarizing muscle relaxant or calcium. The myalgia can be intense and as debilitating as the myalgia produced by an influenza infection. Treatment is supportive, and the pain usually resolves over several days.

## EARLY POSTOPERATIVE SURGICAL PROBLEMS

### Fever

Postoperative fever has several possible causes, which can be remembered as the 4 Ws: wind, wound, water, and walker (Table 64-5). Pyrexia (rectal temperature >101.2°F [38.5°C]) within 24 hours of operation and general anesthesia is common and usually caused by atelectasis. Postoperative atelectasis has many causes. Endotracheal intubation, inhalational general anesthetics, and the use of nonhumidified gases all depress ciliary motion within the tracheal-bronchial tree and

**Table 64-5** Common Causes of Postoperative Fever

SITE	ETIOLOGY	TIME	INCIDENCE	SIGNS AND SYMPTOMS	DIAGNOSIS	THERAPY
Wind (lungs)	Atelectasis	24–48 hr	Very common	Cough, shortness of breath, retractions	Examination, chest radiograph	Cough, deep breathing, incentive spirometer
Wound (operative site)	Infection	>24 hr to 7 days	Rare	Pain, erythema, induration	Examination, wound cultures	Antibiotics, open wound
Water (urinary tract)	Urinary tract infection	3–5 days	Very rare	Dysuria, hematuria	Examination, urinalysis, culture	Remove indwelling catheter, antibiotics
Walker (legs)	Deep vein thrombosis	>3 days	Extremely rare	Swelling, heaviness of lower extremities, superficial venous congestion, palpable cord	Examination, duplex Doppler, venogram	Bed rest, elevation, heparin (Coumadin), thrombolytics

thereby interfere with normal pulmonary clearance mechanisms. When these factors are combined with small tidal volume breathing, somnolence, splinting caused by pain, and cough suppression caused by pain or opioid analgesics, atelectasis occurs. Incentive spirometry alone is not recommended for routine use in the preoperative and postoperative settings to prevent postoperative pulmonary complications. It is recommended that incentive spirometry be used with deep breathing techniques, directed coughing, early mobilization, and optimal analgesia to prevent atelectasis and postoperative fever. Indeed, this feature may be one of the important medical advantages of ambulatory surgery because patients are more likely to be up and about when they are at home rather than in the hospital.

Other causes of postoperative pyrexia are rare. Yeung, Buck, and Filler, in a retrospective analysis of the postoperative course of 256 febrile children at the Hospital for Sick Children in Toronto, Ontario, found that only 4 had infections that required treatment. Interestingly, all 4 of these children had significant and obvious associated signs of infection (local tenderness, crepitation, or erythema at the incision site; tachypnea, cough, dysuria, and headache). Most patients with low-grade postoperative fever require only a physical examination to differentiate between a septic and non-septic process. Extensive (and expensive) diagnostic workups are rarely indicated. Indeed, in most patients, fever in the early postoperative period is so common that it can be regarded as a normal response to operative trauma and general anesthesia. Other unusual causes of postoperative fever include urinary tract infection, dehydration, infected IV access sites, thyroid storm, pheochromocytoma, and malignant hyperthermia. Urinary tract infections do not usually produce symptoms in the immediate postoperative period. Rather, they are a cause of late postoperative fever, usually occurring 3 to 5 days after operation. These children generally are symptomatic and complain of dysuria. Infants may have hematuria. The fever associated with malignant hyperthermia usually starts intra-operatively. Malignant hyperthermia is discussed in more detail in Chapter 63, Preoperative Assessment.

Postoperative wound infections are a potential serious complication. Surgical consultation is recommended as soon as possible so that the appropriate treatment and wound care is provided in a timely fashion.

### Drainage

A small amount of serosanguineous drainage in the postoperative dressing is normal and should not be a cause for alarm. Persistent bleeding requires immediate surgical attention.

Serosanguineous discharge from the operative site 2 to 3 days after the operation may be caused by a superficial hematoma just below the incision site. A hematoma can be recognized by its characteristic ecchymosis and fluctuance. Small hematomas directly below a wound, umbilicus, or scrotum, usually spontaneously drain or resorb. If the hematoma progressively expands, it may then require operative exploration to evacuate the clot and control any ongoing bleeding. In general, a nonexpanding hematoma will usually resolve within 4 to 6 weeks after surgery. If the wound hematoma is associated with pain, then the child should be examined by the operating surgeon.

Serous drainage from a wound may be caused by creation of a large dead space during the operative procedure or by liquefaction of adipose tissue. In general, seromas caused by dead space usually drain 4 to 7 days after surgery, whereas liquefaction of adipose tissue, characterized by yellow drainage, occurs 2 to 3 weeks after surgery.

Regardless of size, hematomas and seromas are excellent culture media for bacteria and increase the likelihood of wound infection. Both of these postoperative problems should be closely watched for and are usually characterized by the triad of pain, wound dehiscence, and persistent drainage.

### Postoperative Bleeding

Persistent bleeding is defined as bleeding or ooze that continues for more than 6 to 8 hours after the operation or a need to change a blood-soaked wound dressing more than twice in the first 6 to 8 hours after

surgery. It almost always indicates inadequate hemostasis and is usually caused by a superficial skin arterial bleeding site, although coagulopathy might also be responsible. Until the bleeding site is investigated and controlled by the operating surgeon or the surgeon's designee, direct digital pressure applied to the wound will slow or stop the flow of blood.

### Post-tonsillectomy Hemorrhage

The incidence of post-tonsillectomy hemorrhage is estimated to be 2% to 4%, with 1% to 2% of patients who have tonsillectomy requiring additional operation. The mortality rate is 1 in 15,000 bleeding episodes. Bleeding that occurs after tonsillectomy may occur early (in the first 24 hours) or late (5–14 days after surgery). Early bleeding is generally caused by failure of hemostasis and may be because of coagulopathy, whereas late bleeding results from dislodgement of the scab from the operative bed. Either form may be severe and life threatening and requires immediate emergency evaluation. Blood clots in the airway may acutely compromise the airway and can be life threatening. Rehydration with isotonic fluid is always required because hemorrhage is frequently associated with history of poor postoperative fluid intake and volume contraction resulting from blood loss. Transfusion, although unlikely, may be required even if a subsequent operation is performed and control of bleeding is achieved.

## MISCELLANEOUS EARLY POSTOPERATIVE PROBLEMS

### Awareness

Awareness refers to a patient's explicit postoperative recall of events during a procedure performed under general anesthesia. The incidence of this phenomenon in adults has been found to be 0.1% to 0.2% in low-risk surgical procedures, but as high as 43% during traumatic surgery. Lopez and colleagues found the incidence of recall in pediatric patients to be 1.2% and as high as 2.7%. Auditory and tactile sensations are most frequently recalled more than pain, anxiety, and paralysis, as in adult patients. Lopez and colleagues also found that the only predictive factor identified was multiple manipulations of the airway. Those children were at an eight times higher risk for developing awareness. This is unlike adults, in whom it has been reported that the use of muscle relaxant or the absence of nitrous oxide in the anesthetic management is a predicting factor for the development of recall.

Many earlier studies have suggested that an extended follow-up is relevant for the detection of awareness. Lopez and colleagues interviewed patients twice during the study, once within 36 hours of the procedure and again 1 month after the procedure. The later interview could help a child elaborate a more coherent and structured representation of the events that took place during the pre-, intra- and postoperative periods.

Previous studies have used the Brice Interview tool for detecting recall in adults. This tool is hardly applicable to children because its contents are not adapted to their cognitive abilities. Lopez and colleagues took

### BOX 64-11 Low Risks for Urinary Retention

- General anesthesia, peripheral nerve blocks, monitored anesthesia care
- Nonpelvic and nonurologic surgery
- Most patients undergoing outpatient gynecologic surgeries (transvaginal, or pelvic laparoscopy) who undergo intraoperative bladder drainage
- Most patients having a spinal, caudal, or epidural anesthesia with short-acting local anesthetic such as lidocaine, procaine, or 2-chloroprocaine

Derived from Souter KJ, Pavlin DJ. Bladder function after ambulatory surgery. *Ambulator Surg.* 2005;12:89–97.

the Brice Interview tool and adapted it to the cognitive capacities of the child being interviewed. They found that this enhanced the detection of awareness in the population studied. (See the Tools for Practice Section for the questionnaire used by Lopez and colleagues.)

### Urinary Retention

In contrast to adults, urinary retention is rare in pediatric surgical outpatients. Most children who undergo surgery through the inguinal canal void within 8 hours of the operation, regardless of their intraoperative anesthetic technique or their postoperative analgesic regimen, which included parenteral and enteral opioids or regional anesthesia (caudal epidural blockade or ilioinguinal-iliohypogastric nerve blocks), or both. This finding is significant because, theoretically, opioids and regional anesthetics, particularly caudal epidural blockade, may interfere with the neural mechanisms responsible for emptying of the bladder. In fact, many investigators who argued against the routine use of caudal anesthesia or opioids (or both) for the treatment of postoperative surgical pain based their opinions on the theoretical risk for urinary retention. Many surgeons, anesthesiologists, and ambulatory care administrators have insisted that children void before discharge after outpatient procedures that require anesthesia. However, many patients simply cannot void on command, particularly in the strange setting of a PACU or hospital. The knowledge that all patients void within 24 hours of operation and virtually all spontaneously void within 10 hours of a procedure strongly suggests that voiding before discharge is unnecessary. Box 64-11 lists common low-risk surgical scenarios for urinary retention; Box 64-12 lists some high-risk scenarios.

To minimize bladder distention, children and adolescents should be encouraged to urinate immediately before coming to the operating room and as soon as possible postoperatively. In some practices, pediatricians and other physicians do not routinely require patients to void before postoperative discharge from the PACU. Exceptions to this rule include patients who complain of lower abdominal distention and discomfort. These patients are initially treated with ambulation, in the case of the older child or adolescent,

**BOX 64-12 High Risks for Urinary Retention**

- Pelvic surgery (hernia, rectal, penile, or urologic)
- Positive family history of retention or spinal cord disease
- Spinal, caudal, or epidural anesthesia with agents of long-acting duration such as bupivacaine, tetracaine, and ropivacaine
- Use of neuraxial opioids combined with local anesthetics

Derived from Souter KJ, Pavlin DJ. Bladder function after ambulatory surgery. *Ambulator Surg.* 2005;12:89–97.

or gentle pressure on the lower abdomen, in the case of infants. If these measures do not lead to voiding and amelioration of symptoms, then bladder catheterization should be performed. Patients requiring bladder catheterization should then be observed for their ability to urinate spontaneously. If bladder function does not return, then the anesthesiologist and the patient's surgeon should decide whether a bladder catheter should be reinserted and if hospitalization is indicated. Nevertheless, the need for bladder catheterization is rare. In the experience of some physicians, urination after outpatient surgery requires a *less is more* attitude; that is, the more attention the physician pays to this issue, the more problems are created.

**Scrotal Swelling**

Scrotal swelling and concomitant discoloration of the scrotum commonly occur after inguinal herniorrhaphy and hydrocelectomy. Initially, this process can produce swelling alone and may progress to bluish discoloration as bleeding and clot lysis occur. In general, the problem is usually the result of bleeding from the cut edge of the peritoneal sac derived from either a hernia or hydrocele. The swelling and color change should resolve in 4 to 6 weeks. However, if fever, erythema, tenderness, and progressive enlargement of the hemiscrotum occur, then an urgent consultation with the patient's surgeon is needed. In many instances, such patients require additional exploratory surgery and operative evacuation of the hematoma through a suprainguinal or trans-scrotal approach.

**LATE POSTOPERATIVE SURGICAL PROBLEMS**

Pyrexia (rectal temperature greater than 101.2°F [38.5°C]) 48 hours or more after outpatient surgery is unusual and may indicate a serious wound infection (see Table 64-5). This circumstance requires evaluation and examination by the patient's physician or, preferably the patient's surgeon. The wound is examined for signs of inflammation, such as heat, pain, redness, and swelling. If any of these signs or symptoms is present, then the operating surgeon should be informed immediately so that appropriate treatment and wound care can be provided.

**BOX 64-13 Risk Factors for Venous Thromboembolism (VTE) in the Postoperative Period**

- Immobility
- Major lower extremity orthopedic surgery
- Spinal cord injury
- Major trauma or trauma to the lower extremities
- Previous history of deep vein thrombosis, VTE, or pulmonary embolism
- Pregnancy
- Oral contraceptive use
- Inflammatory bowel disease
- Nephrotic syndrome
- Burns
- Obesity
- Central venous catheter in the lower extremity
- Known acquired or inherited thrombophilia
- Acute infection

**VENOUS THROMBOEMBOLISM**

Although not as common as in adults, venous thromboembolism (VTE) occurs in children in the postoperative period, with the incidence increasing in adolescence. The physician should be alert to symptoms of VTE, such as extremity pain, swelling, and discoloration, which may indicate deep vein thrombosis and should be referred for immediate evaluation. Patients at highest risk are those who are immobilized after surgery and have at least 1 other risk factor. Risk factors for VTE are listed in Box 64-13. Patients who develop VTE are at risk for pulmonary embolism, which has a mortality rate as high as 20%. Symptoms of pulmonary embolism include dyspnea, chest pain, cough, hemoptysis, and fever. Patients at risk for VTE should receive prophylactic measures, which may include compression stockings or pneumatic sequential compression devices (or both) until ambulatory. Patients with 3 or more risk factors may be treated with pharmacologic prophylaxis: subcutaneous heparin or low-molecular-weight heparin.

**PRACTICAL ASPECTS OF THE POSTSURGICAL WOUND**

Wound healing represents a highly dynamic, integrated series of cellular physiologic and biochemical events. The morphologic events that make up the healing of closed wounds include the following: inflammation, epithelialization, cellular influx, and fibroplasia. The inflammatory phase begins immediately. During its early stages, white blood cells migrate into the wound and engulf and remove cellular debris and tissue fragments. This phase sets the stage for subsequent events in the healing process.

After dead material is removed, the epidermis and dermis immediately adjacent to the wound edges begin to thicken within 24 hours after injury. Within

48 hours, the entire wound surface is reepithelialized. During this critical period, the wound should be kept dressed and dry. Thus, wound dressings are not required after 48 hours. Wound contamination with stool and urine should be cleansed with water or saline, and the overlying dressing should be replaced. Detergent soaps and peroxide should be avoided.

Between days 2 and 3, an influx of fibroblasts into the wound occurs deep in the epithelium. By day 4 or 5, the fibroblasts begin to lay down collagen fibers, which continues for several months. However, remodeling of collagen takes place for more than 1 year. Practically speaking, by postoperative day 4, the wound may be washed with warm water and a bland soap (eg, Ivory, Dove, or Neutrogena). From the surgeon's point of view, all of the morphologic events of wound healing lead to a single important conclusion: wounds become stronger with time. Closing the wound with suture material only serves to hasten the process. Normally, a simple wound will attain 50% of the strength of surrounding uninjured tissue by 28 days. Most wounds are closed using absorbable suture material, which maintains tensile strength for 60 to 90 days, supplies an appreciable amount of wound strength to allow for the normal healing process to take place, and does not require suture removal. Closing wounds with absorbable suture material allows the child to return to activity at an earlier time. For instance, adolescents with uncomplicated inguinal hernia repair may return to nonstrenuous activity 7 to 10 days after surgery and may return to full activity by 4 to 6 weeks. Whenever possible, toddlers are kept off tricycles and bicycles for 7 to 10 days. Infants may be treated with a full bath by postoperative day 4, and there are no restrictions for carrying the infant.

## SCAR FORMATION

Black and white people of Mediterranean descent are predisposed to hypertrophic scars and keloid formation. Keloids are tumors characterized by massive formation of scar tissue in and beneath the skin after any trauma, including surgery. The keloid grows well beyond the borders of the incision, which is what differentiates it from hypertrophic scar formation. Furthermore, a hypertrophic scar tends to resolve with time and, as a rule, is not associated with prolonged itchiness. Keloids tend to recur after excision. Children have a greater tendency to form and re-form keloids than adults. A thorough family history may be a predictor of this pathologic process. An abnormal scar should be observed for a minimum of 6 months postoperatively. If it does not resolve, then a trial excision should be attempted, staying within the confines of the lesion to see what response is obtained. If it recurs, then it should be re-excised and 1% triamcinolone injected beneath the scar, which will produce some keloid resolution. A hypertrophic scar, on the other hand, should be treated with pressure. Overall, the management of the abnormal scar should be determined by the anatomic position of the wound, the age of the patient, and any underlying associated diseases.

Finally, all skin wounds and surgical skin incision sites will scar regardless of the expertise of the surgeon or the use of plastic surgical techniques in closing the skin. Indeed, the notion that plastic surgery is scarless is a myth. Furthermore, the scar tissue will permanently pigment (it will usually become red to dark brown-black) when exposed to intense sunlight during the first 6 months of its formation. Thus, patients and their families should be advised that when going outdoors and exposing the surgical incision site to the sun, the incision site should be completely covered or protected with zinc oxide or a sunblock with a sun-protection factor number higher than 30 for 6 months after surgery.

## MYTHS IN ANESTHESIOLOGY

All clinical practice includes myths and beliefs that are not necessarily founded on hard evidence. False beliefs or myths of any type are rarely written down; rather, they are passed down through generations, leading one to ask: How do these myths or false beliefs develop? Much of the practice of anesthesiology still remains largely a clinical art, with further advancement dependent on quality of research and education.

Some of the more commonly heard myths associated with postoperative care are in regards to pain and are listed below:

- Pain is not harmful.
- Pain relief obscures signs of complications.
- Patients will become addicted to opioids.
- PRN means: "given as infrequently as possible" rather than "give as needed."

Daily activities are not always based on scientific methods. Institutional biases and attending anesthesiologists' personal experiences affect daily practice, and residents are not always taught material that has supporting evidence.

Old myths exist, and new myths will inevitably be born. To minimize their impact on patient care, we must closely scrutinize results of scientific experiments before applying them into our daily clinical practices.

## Chapter 65

# PEDIATRIC REHABILITATION

Lisa H. Shulman, MD; Dona Rani Kathirithamby, MD;  
Maris Rosenberg, MD; Michelle Sirak, MD

*Rehabilitation* is the process of restoring a person with a disability to the fullest physical, mental, social, vocational, and economic usefulness of which the person is capable. When individuals experience neurologic, neuromuscular, or musculoskeletal injuries or dysfunction caused by acquired disease processes (eg, stroke, tumors, severe illness) or trauma (eg, traumatic brain and spinal cord injuries), they are generally candidates for a program of rehabilitation.

*Habilitation* is the process of developing a skill to be able to function in an environment. It may be defined as the process by which various professional services are used to help a person with a disability make maximal use of his or her capacities to function more effectively. The term is also used to refer to various medical, therapeutic, and educational interventions that children with developmental disabilities receive. *Habilitation*, by definition, would be the appropriate term to use in discussing therapeutic planning for children with congenital disorders such as cerebral palsy, spina bifida, or developmental delay. However, using the term *rehabilitation* to refer to both rehabilitative and habilitative services is common practice, given that both processes have the same ultimate goal of optimizing the functioning of the child with a disability.

A *physiatrist* is a rehabilitation physician with expertise in neuromuscular and musculoskeletal disorders. Physiatrists treat injuries and conditions that affect mobility, diagnose and treat pain, and work with individuals to restore maximal function lost through injury, illness, or disability. They treat the whole person and not just the problem area. Physiatrists often lead a team of medical professionals providing nonsurgical treatments for disability.

*Impairment* is defined as any loss or abnormality of physiologic, psychological, or anatomic structure or function. *Disability* is any restriction, limitation, or lack of ability to perform an activity in the manner or within the range considered normal for participation

in life situations. The current World Health Organization Classification of Functioning, Disability and Health (ICF) focuses on comprehensive assessment of disability, combining both medical and social models. The classification system characterizes an individual's *ability for activity and participation* within his or her environment. The goals of treatment include decreasing disability as well as enabling individuals to function optimally in any setting despite their disability by overcoming barriers related to both environmental factors and societal attitudes. For example, in this framework, a child with cerebral palsy would have an *impairment* in terms of motor function, a *disability* or *activity limitation* related to difficulty with ambulation, and *participation restriction* because of difficulty gaining access to buildings that are not wheelchair accessible. However, the child's impairment need not lead to participation restriction if environmental modifications are made (eg, the installation of ramps) that would allow the child to access buildings with ease. This model recognizes that environmental factors and societal attitudes can either limit opportunities for individuals with impairments or facilitate them, thereby eliminating or reducing the participation restrictions resulting from various impairments.

The number of specific disorders resulting in childhood disabilities is vast. Box 65-1 lists a variety of conditions associated with childhood disabilities that are treated with interventions that fall within the realm of pediatric rehabilitation.

Pediatric rehabilitation is also used to treat disabilities that arise as a result of chronic illnesses in children,

## BOX 65-1 Disorders Treated With Pediatric Rehabilitation and Habilitation

### NEUROMUSCULAR DISORDERS (CONGENITAL AND ACQUIRED)

- Cerebral palsy
- Spina bifida
- Myopathies and muscular dystrophies
- Neuropathies (congenital or hereditary, inflammatory, infectious, metabolic) and peripheral nerve injuries
- Congenital and traumatic spinal cord injuries
- Traumatic brain injuries (eg, unintentional injuries, stroke, inflicted neurotrauma)

### MUSCULOSKELETAL DISORDERS

- Arthropathies (eg, juvenile idiopathic arthritis)
- Congenital and acquired limb deficiencies
- Congenital and traumatic orthopedic deformities
- Burns

### DEVELOPMENTAL DISORDERS

- Genetic syndromes
- Developmental delay, intellectual disability
- Developmental language disorders, autism
- Learning disabilities, attention-deficit/hyperactivity disorder

such as sickle cell anemia, human immunodeficiency virus infection, pediatric tumors and malignancies, diabetes, asthma and chronic pulmonary disease, renal disease, and cardiac disease. The following areas are common to approaches in both habilitation and rehabilitation for childhood disabilities: evaluation and management by an interdisciplinary team; identification of areas of functional impairment; development of an intervention plan; and implementation of the intervention plan.

## INTERDISCIPLINARY TEAM

Children with disabilities and their families have multiple, complex needs. Typically, no single professional can manage all of the issues; the care of the child with a disability is best handled by a team of professionals. An interdisciplinary team is made up of professionals from multiple disciplines who collaborate in a climate of mutual respect. The team addresses the full spectrum of the complex needs of the child with a disability by using a family-centered approach. Members of the team dynamically bring together their differing expertise and perspectives to complete a diagnostic workup, create a plan for intervention, and resolve ongoing management issues. The family is a vital member of the team, able to provide information about the settings in which the child spends time, insight into the child's functioning and motivating factors, and clarification of family priorities.

A single member of the team is designated as the primary physician or case manager to serve as the main contact for the family regarding management issues and to bring the family's priorities and concerns to the team. Interdisciplinary teams vary in terms of the professionals involved, depending on the setting and the mission of the team. Interdisciplinary teams function in a range of settings, including acute care hospitals, transitional care units, rehabilitation programs, outpatient rehabilitation facilities, clinics, and home-based programs. Specialty or regional centers may have funding to create larger, more comprehensive teams. In individual communities, a team of a few professionals at different sites may work together, collaborating to create an ad hoc team to assist children and families. Box 65-2 lists common members of the team for children with physical and developmental disabilities.

## IDENTIFYING SPECIFIC AREAS OF FUNCTIONAL IMPAIRMENT, ACTIVITY LIMITATION, AND PARTICIPATION RESTRICTION

After the interdisciplinary team has clarified the diagnoses and impairments for a child with a disability, analysis of function takes priority. Diagnostic evaluation should address all areas of impairment, including the child's general health, sensory impairments, and cognitive impairments because each factor separately, and the impairments collectively, affect the child's ability to execute activities and participate in life situations. Functional evaluation by the interdisciplinary team is essential for establishing treatment goals. Such assessments are typically performed by physicians (eg, pediatric physiatrists and developmental

pediatricians) as well as by physical, occupational, and speech and language therapists. Physical therapists are the experts in interventions to address impairments in gross-motor functioning and mobility, and occupational therapists are the experts in interventions to address impairments in fine-motor and adaptive functioning and self-care skills, whereas speech and language therapists' expertise is in facilitating communication and feeding skills.

The evaluation of gross-motor functioning involves assessing muscle tone, muscle strength, reflexes, sensation, movement patterns, postural status, motor coordination, gait, and joint ranges as well as documenting deformities. This information provides the basis for clarifying impairments and skill level relative to peers. Functional analysis examines the effect of the set of impairments on the child's ability to carry out activities. In the gross-motor domain, the functions of interest include attaining gross-motor skills relating to stability and mobility (sitting, crawling, pulling to stand, ambulating) and transitions from one position to another.

### BOX 65-2 Disciplines Typically Included in an Interdisciplinary Team for Children With Physical Disabilities

- Physiatrist (pediatric rehabilitation specialist)
- Developmental pediatrician
- Primary care physician
- Orthopedist
- Neurologist
- Geneticist
- Otorhinolaryngologist
- Ophthalmologist
- Neurosurgeon
- Urologist
- Pulmonologist
- Physician assistants
- Nurse practitioner and other nurses
- Dentist
- Physical therapist
- Occupational therapist
- Speech and language pathologist
- Feeding therapist
- Psychologist or neuropsychologist
- Special education professional
- Social worker
- Adaptive technology specialist
- Therapeutic recreationalist
- Audiologist
- Nutritionist
- Orthotist
- Prosthetist
- Home health worker

Evaluating fine-motor and adaptive functioning typically involves a detailed history. Children should participate in providing the history as they are able. Functional assessment should involve assessing the child's ability for self-care: feeding, grooming, toileting, hygiene, and dressing. Functional histories should include information regarding areas of competence as well as impairment. Parents are in a unique position to provide details to the team regarding how and where the child currently carries out adaptive tasks, highlighting strengths and strategies that may prove useful in planning interventions.

Many assessment tools can be used to examine motor and adaptive skill attainment. Norm-referenced, standardized tests are primarily diagnostic; they document a set of delays relative to norms, thereby justifying the need for intervention. Examples include the Bayley Scales of Infant Development, Peabody Motor Scale, Vineland Adaptive Behavior Scale, and Bruininks-Oseretsky Test. Functional or qualitative assessments are criterion referenced; they assess how a child performs a task from a functional perspective. Such instruments are useful for intervention planning and follow-up to assess improvement from intervention and ultimately in establishing evidence-based outcomes research. Table 65-1 lists some of the frequently used assessment and functional outcome measures.

## DEVELOPING AN INTERVENTION PLAN

When planning an effective rehabilitation program for a child with a disability, many factors need to be considered. These factors include severity of motor impairment; anticipated functional potential; age, mental capacity, and developmental status; home and family environment; and ethnic and cultural factors.

Realistic goals should be established based on these factors and the lifelong nature of most physical disabilities. The multisystem nature of disabilities often

requires an interdisciplinary approach to treatment with a team of therapists, each therapist using a variety of techniques. The interdisciplinary approach should address the following components:

- Medical management
- Therapeutic management
- Durable medical equipment, orthotics, and prosthetics
- Sports and recreation
- Psychosocial support to the family, caregiver, and patient
- Education and vocational planning
- Transitional and long-term planning

## MEDICAL MANAGEMENT

Medical management of the child with a disability involves the diagnosis and treatment of associated medical issues, pain management, management of spasticity, and complications of tonal abnormalities.

### Associated Medical Conditions

The diagnosis and treatment of associated medical issues are important components of the care of the child with a disability because many common conditions can greatly affect functioning. Common medical issues in children with disabilities relate to growth, feeding and nutrition, vision and hearing, seizures, pulmonary disease (eg, asthma, chronic lung disease), gastrointestinal functioning (eg, gastroesophageal reflux, oral-motor dysfunction, constipation), dentition, behavior, and sleep.

### Pain Management

Managing pain is also an important part of the intervention plan for a child with a disability. Pain can be related to spasticity in neuromuscular disorders such as traumatic brain injury and cerebral palsy; it can be the result of joint inflammation in juvenile idiopathic

**Table 65-1** Functional Outcome Measures in the Assessment of Motor Disability

ASSESSMENT TOOL	AGE GROUP	AREAS OF MEASUREMENT
<b>DIAGNOSTIC ASSESSMENT TOOLS</b>		
Pediatric Evaluation of Disability Inventory (PEDI) <sup>a</sup>	6 mo–7 yr	Assessment: gross-motor, adaptive function Outcome measures: activity and participation
Peabody Developmental Motor Scales <sup>b</sup>	0–9 yr	Assessment: gross-motor, fine-motor, adaptive function Outcome measure: activity
Motor Assessment of Infants (MAI) <sup>c</sup>	0–12 mo	Assessment: gross-motor, reflex function
<b>FUNCTIONAL OUTCOME ASSESSMENT TOOLS</b>		
Functional Independence Measure for Children (WeeFIM) <sup>d</sup>	0–18 yr	Assessment: gross-motor, fine-motor, adaptive function Outcome measure: activity
Gross Motor Functional Measure (GMFM) <sup>e</sup>	15 mo–16 yr	Assessment: gross-motor and fine-motor function
Pediatric Quality of Life Inventory <sup>f</sup>	2–18 yr	Assessment: health-related quality of life

arthritis (see Chapter 324, Rheumatologic Diseases), or it can be caused by sickle crises in sickle cell disease (see Chapter 262, Hemoglobinopathies and Sickle Cell Disease). Pain management is also an integral part of the treatment of burns. For further discussion of pain management, see Chapter 54, Managing Acute Pain in Children; and Chapter 55, Managing Chronic Pain in Children.

### Management of Tonal Abnormalities

Medical management also involves managing tone abnormalities that affect function. This area includes the management of spasticity. The assessment of spasticity should include identifying treatable conditions that can be contributory, such as urinary tract infection, decubitus ulcers, fecal impaction, constipation, and gastroesophageal reflux. Spasticity should not be treated for its own sake but rather when it hinders functioning, causes pain, or interferes with hygienic nursing care or positioning. In many instances, spasticity is beneficial. For example, a child with spinal cord injury may use spasticity in standing. A patient with cerebral palsy may be able to use spasticity to walk.

The spectrum of interventions for managing spasticity includes the use of medication and surgery. Treatment differs depending on whether the spasticity is diffuse or localized. Oral medications such as diazepam, dantrolene sodium, baclofen, and tizanidine have been used for diffuse spasticity, although the functional improvement reported has been modest, in part because of limitation in the dosage that can be used secondary to side effects (mainly sedation). Baclofen, which is administered intrathecally through a programmable pump, achieves higher levels in the cerebrospinal fluid and thus can be effective in managing diffuse spasticity of central origin. Chemodenervation agents such as botulinum toxin A, phenol, and alcohol through injection are indicated for more localized spasticity, especially in younger patients without fixed contractures. Reduction of spasticity is temporary, lasting between 3 and 8 months. Surgical treatment, in the form of selective dorsal rhizotomy, interrupts the afferent limb of the reflex arc, reducing spasticity without causing motor paralysis. Improved range of motion and muscle strength have been reported.

Orthopedic interventions are indicated when medication, splints, casts, and physical therapy have failed to deter the progression of deformities and when spasticity interferes with functioning. Release or lengthening of muscles and tendons can reduce the restricted joint motion or malalignment. Orthopedic interventions should also be considered when fixed contractures interfere with function or when they hinder the provision of nursing care.

Dystonia can occur as a result of genetic causes and in cerebral palsy. It is commonly seen in patients who sustain traumatic brain injury as children rather than adults. The interval between injury and the onset of dystonia varies. Medications such as trihexyphenidyl hydrochloride, carbidopa-levodopa, and bromocriptine are used in treatment of dystonia. Intrathecal and oral baclofen have also been used effectively in treatment of dystonia.

### Complications of Tonal Abnormalities

Orthopedic management also addresses the complications of tonal abnormalities. Spasticity in hip adductors and hip flexors can cause subluxation of hips progressing to hip dislocation or dislocation with degenerative changes of the femoral head with pain. Progressive bony deformities can cause pelvic obliquity and scoliosis of the spine. When hip subluxation is detected, soft tissue release or lengthening can be performed. Comprehensive hip reconstruction may be performed in severely affected children. Orthopedic surgical procedures should be followed by physical therapy and orthotics management to maintain range of motion, strengthen weak muscles, and prevent recurrence of deformities.

## THERAPEUTIC MANAGEMENT

The primary goals of intervention are to maximize functional skills, foster independence, and prevent or minimize complications. The emphasis must be on improved function rather than on improvement in the impairment. No single therapeutic method is suitable for all children; thus, the therapeutic regimen must be individualized to the child.

Components of therapeutic management include physical therapy, occupational therapy, functional activity training, speech and communication therapy, and feeding therapy for oral-motor dysfunction.

### Physical and Occupational Therapy and Functional Activity Training

Children with disabilities often have decreased or limited exercise capacity relative to their typically developing peers. This incapacity may result from the specific pathologic features of their disability, deconditioning, or decreased muscle strength and endurance. In therapeutic management of children, physical and occupational therapists use traditional exercises and specific treatment techniques (both traditional and nontraditional) as well as adaptive equipment and assistive devices to improve muscle strength, endurance, flexibility, and range.

Traditional exercises are often not applicable in the treatment of infants, young children, and older children with significant cognitive impairment because they are unable to cooperate and participate in structured exercises typically prescribed for adults. Therefore, using developmentally appropriate games, toys, and play activities to engage such children is important for improving strength, flexibility, and posture.

Maintaining passive range of motion, flexibility, and joint mobility, as well as preventing soft tissue tightness, is especially important in children with muscle tone abnormalities. Limitation in joint mobility interferes with normal movement and activities. Therapy to elicit active movements in infants is done by handling the child or by inducing spontaneous interaction. Normal movement patterns are facilitated by using developmentally appropriate, colorful toys and equipment. Parents are encouraged to be actively involved because exercise programs must carry over to the home with parents or caregivers performing the exercises daily to maximize benefit.

In preschool- and school-aged children, coordination of therapy with education is increasingly used. Participation of therapists in classroom consultation can enhance the child's education potential. Occupational therapists can assist teachers in improving graphomotor skills, activities of daily living (ADLs), and fine-motor adaptive skills. Physical therapists can assist the child in achieving optimal positioning, trunk alignment, and mobility.

When treating adolescents with disabilities, therapeutic programs are geared toward preventing contractures; maintaining strength, flexibility, and endurance; improving postural alignment; and facilitating mobility. Improving functional skills and increasing independence should be emphasized within the limits of the disability.

In addition to strength training and improvement in range of motion, physical and occupational therapists use specific therapeutic techniques. They rarely use a single approach; rather, therapists combine a variety of approaches to develop a program suitable for a particular child's needs. Many of these treatment approaches have little reliable clinical or scientific evidence to indicate efficacy of one method over another. The outcomes

of various treatments have not been well studied, and assessment tools do not separate the effects of treatment from developmental progress as a result of maturation. The recent emphasis on functional assessment measures and functional outcomes of interventions, along with greater inclusion of children as subjects in outcome studies, have led to an increase in the availability of data that will over time allow for better determination of the effectiveness of various treatment techniques and modalities for children with disabilities. This trend is evident in the relatively large number of recent studies on the use of novel technology-based interventions for physical disability such as the use of virtual reality systems (eg, the Wii) and robotics.

Pediatricians and other primary care physicians are often called on to prescribe therapeutic services for children. Prescribing physicians should have contact with the treating therapists, and be familiar with the goals of the therapeutic program and the techniques that will be used to achieve these goals. If such information is lacking, then the physician should consult with a physiatrist or a developmental pediatrician.

Table 65-2 lists current physical and occupational therapeutic techniques, the populations appropriate

**Table 65-2** Specific Physical and Occupational Therapy Treatment Techniques

TYPE	AGE AND DISABILITY	EMPIRICAL SUPPORT
<b>STANDARD THERAPEUTIC APPROACHES</b>		
<i>Passive stretching:</i> used to prevent deformities and maintain muscle and joint range of motion in children with muscle weakness, spasticity, or medical conditions causing immobility	All ages Used in neurologic, musculoskeletal, and neuromuscular conditions	No clear evidence to support efficacy, or guidance on frequency or duration <sup>a</sup>
<i>Neurodevelopmental treatment<sup>b</sup>:</i> specific patient handling skills, guiding patients through initiation and completion of intended tasks	All ages All neurologic conditions	Few studies Conflicting results
<i>Sensory integration<sup>c</sup>:</i> exercises are used to strengthen the patient's sense of touch, of balance, and of where the body and its parts are in space	Children with CP, ID, autism, developmental delay, ADHD, LD, developmental coordination disorder	Many studies Conflicting results <sup>d</sup>
<i>Conductive education<sup>e</sup>:</i> methods focus on educating the child to learn how to gain control over his movements; uses unique equipment and group instruction with a specially trained "conductor"	Preschool- to school-aged children with CP, spina bifida, neurologic disorders	Many studies Conflicting results
<i>Constraint-induced therapy:</i> for hemiparesis; the technique involves restraining the uninvolved arm and engaging the paretic arm in intensive motor practice and shaping	Adults and children with hemiparesis because of CP or stroke	Evidence based <sup>g, h, i</sup>
<b>TECHNOLOGY-BASED APPROACHES</b>		
<i>Partial body weight–supported treadmill training (PBWSTT):</i> twice-weekly sessions targeting walking speed and endurance	Children through age 6 yrs with CP, developmental delay, ID	Emerging evidence <sup>j</sup>
<i>Virtual reality systems:</i> for example, Wii habilitation	Adults and children with TBI, CP, hemiparesis	Few studies Conflicting results <sup>k-n</sup>
<i>Robot assistive therapy:</i> use of robotics to move the child's body through normal movement patterns	All ages with spasticity	Few studies, but promising <sup>o-q</sup>
<i>Aquatic therapy:</i> pool-based treatment program provided by a licensed therapist focusing on strength training, muscle relaxation, stretching, and opportunity and motivation for activities the patient may be unable to perform on land. Indications include muscle weakness, decreased range of motion, impaired coordination, and poor endurance.	CP, spina bifida, arthritis, TBI, strokes, burns, fractures, and asthma Contraindications: open wounds, infectious skin conditions, temperature instability, uncontrolled seizures, hypertension, hypotension	Some evidence <sup>r</sup>

**Table 65-2** Specific Physical and Occupational Therapy Treatment Techniques—cont'd

TYPE	AGE AND DISABILITY	EMPIRICAL SUPPORT
<i>Hippotherapy</i> : a licensed therapist uses the characteristic movement of a horse to provide graded motor and sensory input designed to increase muscle strength and motor skill achievement	CP, spina bifida, TBI, spinal cord injury, amputations, neuromuscular disorders, Down syndrome Contraindications: spinal pathology, poorly controlled seizures, severe cognitive or behavior impairment	Improvement in function in CP, decreased frustration and aggression <sup>s-u</sup>
<b>ALTERNATIVE MEDICINE APPROACHES</b>		
<i>Craniosacral techniques</i> <sup>v</sup> : manipulative hands-on technique, whole-body method of relaxing restrictions around the brain and spinal cord to enhance CNS perfusion and allow the body to self-correct	Originally used for adults, now used in children with cerebral palsy	Few studies No evidence of efficacy in children with CP
<i>Adeli Suit therapy</i> : a device developed in Russia resembling a cosmonaut suit. The suit's components are connected by bands that can be adjusted to imitate flexor and extensor patterns of major muscle groups to correct abnormal alignment. Treatment is given multiple times per week at high intensity for a 4–6 week period.	CP	No evidence of efficacy in children with CP <sup>w</sup>
<i>Hyperbaric oxygen therapy</i> : based on the theory that there are dormant areas surrounding the injured areas of the brain in children with CP and related neurologic disorders that can be stimulated with higher concentration of oxygen. Treatment consists of delivery of oxygen at high pressures for up to 40 1-hour sessions.	CP and other neurologic disorders	No evidence of efficacy; risks of treatment include rupture of ear drums, bleeding, and in rare circumstances death <sup>x</sup>

ADHD, attention-deficit/hyperactivity disorder; CP, cerebral palsy; ID, intellectual disability; LD, learning disability; TBI, traumatic brain injury.

to receive these therapies, and the availability of data to support them. Many of these therapy techniques were originally used in adults and have been modified for children.

Physical and occupational therapists use various modalities in conjunction with therapeutic exercises, such as electrical stimulation, biofeedback, therapeutic cold and heat, hydrotherapy, and dry heat therapy. Electrical stimulation can be used to treat muscle spasms and to improve functional skills as part of gait training or programs targeting upper extremity usage. Biofeedback, with and without electromyography feedback, can help patients learn ways to gain control over motor function. Therapeutic cold decreases the muscle stretch reflex excitability and clonus and improves range of motion. It can be used to decrease spasticity temporarily and to allow mobility of extremities during therapy. In children with arthropathies such as juvenile idiopathic arthritis, hydrotherapy, hot packs, and dry heat therapy can relieve joint stiffness and pain and allow active range of motion of involved joints.

Hyperbaric oxygen therapy, intensive suit therapy (Adeli), magnetic therapy, and acupuncture are non-traditional therapy techniques used in many children with neurologic disease that lack evidence-based support.

Functional activities training is a critical component of the therapy program, especially for older children and adolescents. The training focuses on age-appropriate ADLs, such as dressing, feeding, brushing teeth, and personal hygiene. Actual training goes on during therapy sessions. Adaptive equipment such as long-handled hairbrushes, modified toothbrushes, and special utensils should be provided. Carryover to home and practice are critical. Bicycling, stair climbing, treadmill walking, and virtual reality system activities should be encouraged as tolerated to improve mobility, endurance, and strength.

### Speech and Communication Therapy

The indications for speech and language therapy in children include developmental language delays such as those associated with intellectual disability, autism, and hearing impairment; acquired language disorders caused by neurologic disorders such as traumatic brain injury, stroke, brain tumor, or encephalopathy; and speech disorders resulting from neuromuscular processes that involve respiration, phonation, articulation, structure, and function, such as in cerebral palsy, myopathies, tracheostomy, ventilator dependency, and high spinal cord injuries. (For further information, see Chapter 195, Speech and Language Concerns; and Chapter 226, Cerebral Palsy.)

### Oral-Motor and Feeding Therapy

These same groups of children and adolescents should be assessed for oral-motor dysfunction, which affects feeding and swallowing. Oral-motor dysfunction can be temporary (debilitative illness) or long term (neuromuscular disorder). Successful feeding involves the coordinated action of multiple systems. Normal feeding requires anatomic integrity of the oropharyngeal cavity, neuromotor control and coordination, sensory

perception, adequate gastrointestinal function, sufficient cardiorespiratory support, intact autonomic nervous system, and integration of normal behavioral responses. Therefore, assessment and intervention in feeding disorders require an interdisciplinary approach. The team of specialists with expertise in feeding may include speech and language pathologists, occupational therapists, nutritionists, gastroenterologists, otorhinolaryngologists, radiologists, physiatrists, and developmental pediatricians.

Warning signs for the pediatrician regarding the possibility of a feeding or eating disorder include the following:

- History of frequent respiratory infections
- Difficulty handling oral secretions and drooling
- Coughing and choking
- Multiple swallows to process a bolus of food
- Noisy breathing
- Food refusal
- Failure to thrive

Assessment of oral-motor function includes a detailed feeding history, observation and assessment of current feeding behavior and skill level, and nutritional status. The oral-motor structures should be examined for anatomic abnormalities of the oral cavity and for functional abnormalities of the lips, tongue, and jaw. Such abnormalities may be caused by the presence or absence of normal or abnormal oral reflexes necessary for coordinated feeding (eg, tongue thrust), weakness or incoordination (eg, poor lip seal), or pain (eg, temporomandibular joint syndrome). The evaluation may require assessment of oropharyngeal structure and function with video fluoroscopy or fiberoptic endoscopic evaluation of swallowing (FEES) to assess for structural abnormalities or evidence of aspiration. This information is often required before feeding therapy can safely be initiated. The child should be evaluated for the ability to manage oral and pharyngeal phases of swallow as well as the ability to swallow foods of different consistencies.

Poor motor control of the head, trunk, and extremities can also interfere with feeding. Muscle tone abnormalities, opisthotonic posturing, obligatory primitive reflexes, and abnormal movements can all interfere with proper positioning. Sensory abnormalities such as hypersensitivity or hyposensitivity to food texture or utensils used for feeding or inability to tolerate being handled or held can also interfere with successful feeding. Medical factors such as gastroesophageal reflux disease, seizures, swallowing dysfunction, or respiratory distress can cause pain, lethargy, and agitation, all leading to food refusal. When feeding difficulties are longstanding as a result of any of the previously mentioned abnormalities, behavioral feeding problems can result, including refusal to participate in oral feeding or selective or restricted intake, leading to inadequate nutrition.

Treatment of feeding difficulties includes an initial decision regarding the child's ability to eat safely and effectively. If significant obstacles to safe oral feeding are identified, then enteral feeding may be indicated. Feeding competency can be encouraged through the use of adaptive positioning chairs with head and trunk supports for positioning of children

with poor head control and impaired trunk balance; the use of specialized nipples, bottles, feeders, or adaptive shallow spoons; the use of special cups to improve lip closure and sucking movements; and the use of brushes for oral stimulation to diminish hypersensitivity. For the child with food refusal, any medical factors affecting motivation for feeding must be addressed. After medical conditions have been treated and positioning and adaptive feeding equipment optimized, if feeding refusal persists, a behavioral feeding program is recommended. Such programs are often intensive, with inpatient and outpatient models.

The inability to feed and swallow is a difficult experience for children and families, and it can have far-reaching consequences. It can interfere with parent-child interaction and attachment, especially in infants. In older children, it can result in isolation owing to an inability to share social experiences at mealtimes with friends and family.

## DURABLE MEDICAL EQUIPMENT

*Assistive technology* or *durable medical equipment* (also called adaptive equipment) refers to equipment designed to enhance the independence of children with chronic illnesses and disabilities, thus improving their quality of life. Assistive devices can be divided into categories based on their intended function: positioning, mobility, ADLs, communication, and support.

*Positioning devices* promote optimal posture and alignment of joints in children who have not achieved adequate head or trunk control. They prevent contractures and decubitus formation by decreasing pressure on bony prominences. Devices such as *positioning chairs* serve as an alternative to beds or wheelchairs and allow the child to be optimally positioned during interactions with others, such as at mealtime or during other family activities. *Standers* provide supported passive standing for children who cannot independently bear their own weight.

*Mobility devices* can be subcategorized into ambulatory aids, transfer aids, and wheeled mobility aids. Ambulatory aids such as walkers help children improve balance and posture, provide support during walking, and decrease energy expenditure. *Forward* or *anterior walkers* promote trunk flexion; *reverse* or *posterior walkers* facilitate more erect posture and trunk extension. Crutches and canes are mobility aids that can be used by children who have better trunk control. Before children use ambulatory aids at home, they should be trained by a physical therapist. The devices must be checked and adjusted regularly to accommodate the growth of the child.

Transfer aids are used to assist children in changing their position on one surface or in transferring from one surface to another. An example is a *trapeze bar* over a bed.

Wheeled mobility devices, such as wheelchairs, scooters, and strollers, are designed to meet the diverse needs of children with differing levels of physical disabilities, cognitive limitations, and recreational interests.

Proper selection of a wheelchair is essential. Manual and powered wheelchairs share the same basic

components: frame, seat, wheels and tires, armrests and footrests, brakes, and seat belts. Powered wheelchairs should be considered for children with adequate cognition (a developmental level of at least 24 months) whose upper body strength or endurance is insufficient to propel a manual chair effectively. The child must be able to understand the concept of cause and effect, be able to follow 1-step commands, have adequate visual skills, and have at least one reliable movement for activating a switch to operate the powered chair. Powered chairs can be operated with joysticks, head or chin switches, track balls (in the setting of weak grasp), and sip-and-puff mechanisms. There are mechanisms to elevate and recline seats, change position from sitting to standing. There are 3-wheel and 4-wheel power scooters available when there is insufficient space at home to maneuver a power wheel chair.

*ADL devices* help patients during feeding, bathing, grooming, and toileting. Occupational therapy evaluation determines the need for such devices, which are used in conjunction with a therapeutic program appropriate for the child's age and functional level. Parents should be involved in the therapeutic program to provide implementation assistance and supervision of these activities.

*Communication devices* use augmentative and alternative communication strategies when a child's ability to speak is impaired. Taking into account the child's cognitive ability, these devices range from simple to complex and should allow expansion if the child's communication abilities improve.

*Support Orthoses* are externally applied devices that are used to modify structural and functional characteristics of the neuromuscular and skeletal system of the body. In clinical practice, orthoses generally take the form of splints or braces. Common aims in prescribing orthoses are to provide optimal positioning and maintain correct alignment of an extremity, prevent deformities by restricting abnormal joint motion, correct joint contracture, relieve discomfort, and assist in function and stability. An orthosis may be rigid and support an affected extremity in one position (static), or it may allow movement in a controlled manner (dynamic). Orthoses can be used for both upper extremities (eg, finger-thumb adductor splints, elbow extension orthoses, shoulder stabilization orthoses) and lower extremities (eg, supramalleolar orthoses, ankle-foot orthoses).

*Splints* are commonly made of low-temperature thermoplastic materials that are heated and molded directly onto an extremity. They are flexible and less durable. Splints are generally used for upper and lower extremities in infants and young children and for upper extremities in older children. They can be easily modified and adjusted to accommodate rapid growth and are cost-effective. *Braces* are usually custom made from high-temperature plastic materials cast from a plaster mold, metal joints, and leather or canvas straps with buckles or Velcro. Braces are durable, but they cannot be easily adjusted to accommodate growth; therefore they need to be replaced after a growth spurt or a change in neuromuscular or functional status.

A recent assistive technology innovation with promising results involves the use of a functional

electrical stimulation (FES) device. Generally, FES is used in cerebral palsy, in poststroke patients to improve function in hemiplegic upper and lower extremities, and in spinal cord injuries. In multiple sclerosis, FES is used for foot drop. FES is used to complement physical therapy to improve strength. A recent study in the *Journal of Spinal Cord Medicine* suggested that lower extremity FES cycling promotes physical and neurologic recovery in chronic spinal cord injury.

With the assistance of the treating therapist, physicians provide a letter of medical necessity and prescription for orthoses. Orthoses are fabricated either by an orthotist or by qualified and experienced physical and occupational therapists. Comfortable fit will improve acceptance. Cotton socks or stockings should be worn under the orthosis to absorb perspiration. A realistic wearing schedule must be outlined with gradually increased periods of use, from a few minutes to the desired number of hours. Skin should be examined for evidence of increased pressure (especially over bony prominences), edema, or other inflammatory responses.

Unbiased clinical research regarding the effectiveness of orthoses or even the spectrum of their application has been sparse. In children with cerebral palsy, a short-term effect on passive range of movement and diminished toe walking have been reported, but the long-term clinical significance is unclear.

## SPORTS AND RECREATION PROGRAMS

Physical benefits of exercise in adults with disabilities (eg, adult paraplegia) have been documented. Individuals with disabilities who are involved in exercise programs have fewer decubitus ulcers, decreased incidence of urinary tract infections, and fewer hospitalizations. Improved strength, endurance, range of motion, and flexibility have been described in patients with cerebral palsy, as have increased socialization and higher self-esteem.

Less information is available regarding effects of sports and recreation activities on children with disabilities. Children with disabilities are found to generally watch more television than their peers. Encouraging data show that self-concept scores of young athletes with disabilities were similar to their able-bodied peers. Sports can be a significant part of an active lifestyle for children with disabilities. Adapted sports are activities that have been modified to meet the needs of children with disabilities. Adapted physical education was developed as a result of the Individuals With Disabilities Education Act of 1973 (IDEA), which includes instruction in physical education as a part of the child's individualized education plan.

Sports for youth with disabilities are available in many communities through community centers, summer camps, and after-school programs and through adapted physical education programs. Such activities can be therapeutic, recreational, or competitive.

Training is provided for teachers, therapeutic and recreational specialists, and physical and occupational therapists in identifying needs, developing curricula, and providing direct instruction in adapted sports.

Physical education teachers provide early exposure to sports and recreational activities for children with special needs, and they encourage participation at local, regional, and national levels as the children mature.

Therapeutic sports include hippotherapy (horseback riding for individuals with disabilities), aquatic therapy, dance therapy, yoga, tai chi, and karate. Hippotherapy has been popular in Europe since the 1950s and has been used in the United States since the 1970s for children with cerebral palsy. The concept behind the intervention is that the movement of the horse induces a pattern of movement in the rider similar to human walking. Reported benefits include improvement in muscle tone, posture, balance, and strength as well as improved concentration, language skills, self-confidence, and peer relations. Aquatic therapy uses water therapeutically. The increased buoyancy of water diminishes the effect of gravity; thus, less effort is required to move. The temperature of the water can therapeutically relax muscles. Increased range of motion and improvement in coordination, cardiorespiratory endurance, and muscle tone have been noted.

Many children with disabilities participate in organized athletic events. The Special Olympics, Paralympics, National Wheelchair Athletic Association, National Wheelchair Basketball Association, American Athletic Association of the Deaf, and United Cerebral Palsy Athletic Association have established junior-level participation and programs for athletes with disabilities 6 to 18 years of age.

With the expansion of the range of competitive sports for athletes with disabilities, sports classification systems have been developed to allow for competition among athletes with various disabilities. Early classification was based on medical diagnoses. The current classifications are based on functional skills; therefore, athletes with different disabilities compete in a single system.

Children with disabilities face many challenges when participating in adapted sports as a result of their medical conditions, varying functional skill levels, and sometimes the need for sophisticated and expensive individualized equipment. For example, a child with spina bifida or a spinal cord injury can have decreased or absent sensation, which may result in pressure ulcers or skin breakdown as a result of minor stresses. An athlete with cerebral palsy may be predisposed to developing muscle strains and injuries as a result of abnormal stresses on spastic muscles and joints with decreased range of motion. A child with mobility impairment may require a racing or sports wheelchair, adapted skis, special balls, or safety devices for participation in the child's chosen activity.

Athletes must first be evaluated to assess their muscle strength and coordination and then to assess their ability to participate in the specific competitive sport. As with able-bodied athletes, children with disabilities should have a preparticipation history taken and a physical examination performed. Medical issues, disability-specific concerns, and developmental and behavioral issues should be addressed. General

health, conditions limiting participation, and predisposing factors to injury should also be assessed.

## PSYCHOSOCIAL SUPPORT TO THE FAMILY AND PATIENT

The family is a pivotal member of the interdisciplinary team. The principles of family-centered care are central to the planning and delivery of care for a child undergoing rehabilitation. These principles include treating families with respect and dignity and listening to and honoring family perspectives, choices, values, beliefs, cultural background, and knowledge. Families are encouraged and supported in participating in care and decision making at the level they choose. Although family members are experts on their child and the priorities and concerns of the family, they are often students—at least initially—in the diagnostic and treatment aspects of rehabilitation. Psychosocial support is needed to address parents' thoughts, feelings, questions, and concerns as they make their way through the rehabilitation process. The patient, depending on age and developmental capacity, should also be included in the psychosocial support plan. The individual learning styles and educational levels of the caregivers and the patient need to be taken into account when working with families, and education should include presentation of materials through different modalities. Because of anxiety and stress during the course of treatment, remembering complicated information may be hard for a caregiver; therefore, staff members should teach skills gradually and repeatedly. Families are most satisfied when care is offered in a respectful and supportive manner.

Providing psychosocial support to the family and child is an integral part of the rehabilitation plan. Support must be flexible and individualized to meet the family's changing needs. The times of greatest need are typically at the initial diagnosis and at points of transition. When a child is newly diagnosed with muscular dystrophy or has experienced traumatic brain injury, the family may cope with guilt, anger, and the loss of what might have been. Transitions from one setting of care to another, such as the discharge of a premature infant from the neonatal intensive care unit or the transition from the hospital setting to the home, a rehabilitation facility, or a transitional care unit after traumatic brain injury, are points of particular stress for families. Parents may feel anxiety or stress as a result of changes in their child's level of care. They may feel unprepared for the new setting, time of discharge, or management of their child's new medical and equipment needs.

To provide support to the family most effectively, family members should be engaged in the planning process early on to ensure coordination and continuity of care from one setting to another. Optimal support to families includes an effective and collaborative discharge plan. This plan includes the identification of the patient's primary caregivers and an understanding of family beliefs, attitudes, motivations, competency, social supports, and biopsychosocial stressors in the home environment. In addition, an assessment of the home environment, home equipment, and service

needs and provision of appropriate home care and community support services (eg, nursing services, home-based therapies, durable medical equipment, school accommodations, backup care in the community) will facilitate a smoother transition process for the patient and family. Alternative therapeutic plans may need to be explored with the family and interdisciplinary team when barriers preclude a safe and agreed-upon treatment plan.

In-hospital supportive counseling, parent-to-parent groups, home modifications, and training in equipment use and rehabilitation needs can support, strengthen, and encourage the family's ability to care for the child at home or during transition from the acute care setting to a transitional or rehabilitation unit. A trial home visit from a rehabilitation facility may build the family's confidence and self-determination in preparation for discharge, with the availability of the interdisciplinary team to provide support and further education to the patient and family as needed.

## EDUCATIONAL AND VOCATIONAL PLANNING

When transitioning a child to the home, additional support in the community must extend to the academic setting to ensure appropriate placement, related services, and accommodations as needed. State agencies such as Vocational and Educational Services for Individuals With Disabilities provide vocational training to prepare the adolescent or young adult for suitable jobs. (See Chapter 52, School-Related Issues for Children With Special Health Care Needs.)

## IN THE COMMUNITY: ACCESSING THERAPEUTIC AND MEDICAL SERVICES

Beginning in the neonatal intensive care unit and continuing through adulthood, entitlements exist that families can access to obtain therapeutic services for their children with disabilities and to fund these services. Early Intervention, Part C of IDEA, funds evaluation of children from birth to 3 years for developmental disabilities, designation of a service coordinator, and provision of a wide range of therapeutic services for the eligible child and the child's family. Typically, children who are 3 years of age and showing continued impairment may enter either a therapeutic nursery setting or a regular child care or nursery and receive therapies at those sites. IDEA ensures that rehabilitation services continue into elementary school and through 21 years of age. Although these entitlements can provide an array of therapies to children with disabilities, they only address a portion of the necessary intervention plan for the child with a disability as described in this chapter. Meeting the needs of the child with a disability requires an interdisciplinary team that is able to integrate health care and therapeutic services in a coordinated fashion. This task is best accomplished through care coordination centered in the medical home.

Many potential obstacles can hinder families attempting to obtain care for children with special health care needs. The American Academy of Pediatrics policy statement Care Coordination in the Medical

Home: Integrating Health and Related Systems of Care for Children With Special Health Care Needs cites multiple barriers to effective care coordination, including:

- Lack of knowledge and information about the chronic condition
- Lack of community resources and a coordination process on the part of the primary care physician
- Primary care physicians who feel unprepared to be involved in equipment decisions for physically impaired children in their care
- Lack of communication between health care providers and other organizations involved in the child's care
- Lack of clearly defined roles for each team member, leading to redundancy of efforts and gaps in care
- Inadequate time and reimbursement for the administrative tasks associated with care coordination
- Language and cultural barriers between health care providers and families

Obstacles to accessing services can also be related to the family of a child with a disability. Although families who are knowledgeable about their child's condition can often effectively coordinate care, some families require more assistance with this task as a result of language barriers, educational level, economic situations, lack of insurance, or living far from sites of available specialty medical care. An effective, coordinated system of care must address these obstacles.

## Chapter 66

## TRANSITIONS TO ADULTHOOD

Paul J. Sagerman, MD, MS

Sections of this chapter have been excerpted from the clinical report Supporting the Health Care Transition From Adolescence to Adulthood in the Medical Home, published in *Pediatrics* in 2011, with the permission of the American Academy of Pediatrics (AAP). The author of this chapter was a co-lead author of the clinical report and wishes to acknowledge the contributions of that document's authoring group to this chapter.

### INTRODUCTION

Transitions occur throughout life and are often highly anticipated: fetus to newborn, preschool to kindergarten, high school to college, single to married, and so on. The foremost responsibility of parenthood is the provision of a safe and stimulating environment wherein children can gain experiences and acquire those skills that will allow them to transition into a successful and productive adult life.

The ability of a child to fully achieve his or her potential is among the cornerstones of good pediatric health care. Delivery of developmentally appropriate

health care before, and continuing throughout, the transition from adolescence into young adult life is paramount to maximizing lifelong function, both physically and psychosocially. This is true for all youth with and without special health care needs. Paramount to a successful health care transition, pediatric and adult providers must clearly differentiate between the terms *transition* and *transfer*. *Transition* is a “process,” occurring over time, which may vary from patient to patient. *Transfer of care* is an “event,” which involves the actual handing off of patient care responsibilities from the pediatrician to the physician.

This chapter aims to facilitate the practice-based implementation of planning, decision-making, and documentation processes for youth who are approaching transition—including those who have special health care needs and those who do not. It summarizes the intent of the 2011 AAP clinical report *Supporting the Health Care Transition From Adolescence to Adulthood in the Medical Home* to provide a structure for training, continuing education, and research to further the understanding of best practices for transition of adolescents to adult care. It does not detail the activities conducted by *receiving* providers who accept patients into an adult model of medical home care.

## 2002 CONSENSUS STATEMENT

A consensus statement coauthored by the AAP, the American Academy of Family Physicians (AAFP), and the American College of Physicians—American Society of Internal Medicine (ACP-ASIM) published in 2002, clearly supports a timely and integrated transition of special needs youth into adulthood. This consensus statement focused on transition from the perspectives of pediatric and adult medical providers, patients, and caregivers. Barriers to transition were identified, and gaps in social, political, and fiscal viability for transition programs were addressed. The consensus statement identified 6 critical steps (Box 66-1) to improving adolescent transition, which have become widely recognized tenets of research, practice models, and policy implementation in the years since its publication.

After more than a decade of effort, the widespread implementation of health transition supports as a basic standard of high-quality care as part of the medical home approach has not been realized. To date, there has been only limited achievement of national health policy goals related to transition. Outcomes-related research efforts have, so far, failed to fully address the transition needs of adolescents with or without chronic conditions. A recent national survey demonstrated that pediatricians remain poorly informed about the conclusions of the consensus statement and that most pediatric practices neither initiate transition planning early in adolescence nor offer transition support services, which have been found to be critical for ensuring a smooth transition to the adult health care model. The survey authors note that “gaps in transition support are due in part to limited staff training; lack of an identified staff person responsible for transition; financial barriers; and anxiety on the part of

### BOX 66-1 2002 Consensus Statement: Six Critical Steps

- Ensure that all young people with special health care needs have an identified health care professional who attends to the unique challenges of transition and assumes responsibility for current health care, care coordination, and future health care planning. This responsibility is executed in partnership with other child and adult health care professionals, the young person, and his or her family. It is intended to ensure that as transitions occur, all young people have uninterrupted, comprehensive, and accessible care within their community.
- Identify the core knowledge and skills required to provide developmentally appropriate health care transition services to young people with special health care needs and make them part of training and certification requirements for primary care residents and physicians in practice.
- Prepare and maintain an up-to-date medical summary that is portable and accessible. This information is critical for successful health care transition and provides a common knowledge base for collaboration among health care professionals.
- Create a written health care transition plan by age 14 years together with the young person and family. At a minimum, this plan should include what services need to be provided, who will provide them, and how they will be financed. This plan should be reviewed and updated annually and whenever there is a transfer of care.
- Apply the same guidelines for primary and preventive care for all adolescents and young adults, including those with special health care needs, recognizing that young people with special health care needs may require more resources and services than do other young people to optimize their health.
- Ensure affordable, continuous health insurance coverage for all young people with special health care needs throughout adolescence and adulthood. This insurance should cover appropriate compensation for health care transition planning for all young people with special health care needs, and care coordination for those who have complex medical conditions.

pediatricians, adolescents, and their parents about planning for their future health care.” Other authors have cited, as a barrier to transition, the lack of developmentally appropriate tools to assess child and family readiness for transition. The result is that many pediatricians, youth, and families have found a limited availability of adult providers with whom to partner to arrange a smooth transition of care.

Where there are obstacles, there are also opportunities. Lacking a nationally accepted “gold standard” for transition, foremost among these opportunities is the flexibility to create transition platforms that may have a few common modalities but respond to the individual needs of the adolescent patient. Providers have opportunities to establish their own local and regional networks with adult medical services, with

the aim of building and establishing systems that can then be used by others. This chapter provides pediatricians a starting point for brainstorming ideas that might work best within their own unique medical home environments. The need is stronger than ever for the seamless transfer of care and personal health information from pediatric care settings to more adult settings and for all youth to function as independently as possible in promoting their own health as adults. The 2007 AAP Annual Leadership Forum designated as a top 10 priority the resolution “transitioning youth with special health care needs to adult health care.” *Bright Futures* provides a framework for anticipatory guidance throughout childhood and adolescence that encourages parental support of self-management and independent decision-making about health.

## AMERICAN ACADEMY OF PEDIATRICS CLINICAL REPORT

In 2011, the AAP convened an authoring group that produced the clinical report *Supporting the Health Care Transition From Adolescence to Adulthood in the Medical Home*. Like its predecessor consensus statement, the clinical report authors represented the 3 primary care medical societies (AAP, AAFP, ACP-ASIM), as well as patient and parent advocacy organizations and the federal government’s Maternal and Child Health Bureau. All 3 professional groups recognize the need to translate the principles of the 2002 Consensus Statement into practical operational guidance for the care of all children and youth as they transition to adulthood. Although youth with special health care needs require a broader range of considerations during their transitions, all youth need education, guidance, and planning to prepare to assume appropriate responsibility for their own health and well-being in adulthood. Most youth with chronic illnesses will survive into adulthood and, depending on the severity and specifics of their disability, should transition to an adult model of care for primary and most specialty care in both outpatient and inpatient settings. After the age of majority, all youth deserve to be treated as adults and to experience an adult model of care—although some individuals may require some level of decision-making support from a third-party proxy, such as through guardianship or power of attorney. Recent evidence has shown that higher executive function affecting impulsivity and decision-making continues to mature through the mid-20s. Older adolescents and young adults may require guided decision-making assistance from physicians and family members as they enter adult systems of care. Nevertheless, most youth will benefit from advance planning and preparation for that experience, regardless of whether they remain with their pediatrician or medical subspecialist after 18 years of age.

The AAP *Clinical Report* advocates an algorithmic approach that focuses on addressing issues from the viewpoint of the 3 main stakeholders in transition: the patient, the patient’s family, and the medical providers (both the outgoing pediatrician and the incoming physician). This report assumes that it is the youth, not the

physician, who is transitioning in his or her movement from one stage of life and development to another. The actions of the youth’s medical home involve not only planning for the *transition* of care by defining roles with the youth and family but also the *transfer* of some or all elements of care to an adult medical home setting or, in the case of a family medicine practice, to an adult medical home model. The medical home visit is a different process when the patient has reached the age of majority; adult patients have specific considerations and necessitate attention to new requirements, such as adopting consent for treatment processes and Health Insurance Portability and Accountability Act (HIPAA)-compliant forms. Health care transfer is one element of transition and has a defined content endpoint that may vary in age from patient to patient. Because both transition and transfer are influenced by environmental, socioeconomic, medical, and other factors, it is the responsibility of the medical home—in partnership with patients and their families—to coordinate efforts that ensure optimal outcomes for every patient.

## TRANSITION PLANNING

### Pediatrician and Physician Readiness

A key component in the primary care medical home’s support of the transition process is an explicit office policy describing the practice’s approach to health care transition, including the age and process by which youth shift to an adult model of care. This office policy applies to all youth (both with and without special health care needs), guides the process, and helps the youth and family members (or other caregivers) understand the medical home team’s roles and responsibilities as well as their own. The office transition policy should be visible and readily available to both patients and their families; it may be included in brochures, posters, or Web-based information about the practice. This office policy should clearly describe the goal of transition as part of lifelong preparation for a successful adult life and articulate how the early and ongoing process of transition planning facilitates the patient’s movement from a pediatric to an adult care mode.

### Family Readiness

The transition process is complex and potentially emotional for parents and other caregivers and guardians. Medical home team members must understand patients’ and parents’ perspectives and address their needs during transition. Although families make multiple transitions during their children’s lives, for many parents the pediatrician has been a constant, and departure from the known to the unknown may be stressful. This is particularly likely for parents of children with special health care needs. To make the process smoother for all involved, transition planning must anticipate challenges that parents may face as the youth enters adulthood.

Pediatricians should educate parents and youth and school staff about their roles in supporting the transition process. This education should include information about how the health care environment changes

when the youth legally becomes an adult and differences between pediatric and adult medicine models. The physician's goals are to normalize the transition process, address the families' concerns and questions, and foster a team approach to help facilitate the acquisition of skills and tools that the youth can use in transition and beyond. The family members or other caregivers should be engaged and open to the process (eg, learning about any upcoming changes in health coverage), encourage autonomous decision-making and self-care on the part of the youth, and share their questions or concerns with the physician as they adjust to their shift from primary decision maker and caregiver to a more supportive role.

### Youth Readiness

For transition planning to succeed, pediatricians, physicians, and parents or caregivers must view the youth as drivers in the process, encouraging youth to assume increasing responsibility for their own health care. Empowering youth through transitions fosters the development of self-management skills and tools needed for individuals to gain more control over their lives. This is particularly critical for youth with special health care needs, who may require a broader range of considerations during the transition process.

Although the clinical report presents optimal ages for initiating and conducting transition planning, it is never too early to begin conversations among the pediatrician, family or caregivers, school staff, and patient about planning for the future—again, especially for children with special health care needs. For this population, similar conversations may occur in the educational system regarding Individualized Education Plans (IEPs), when appropriate. These conversations should reinforce and buttress each other. Prioritizing and reinforcing the value of independence and decision-making as part of the transition planning process not only reinforces such messages on the part of providers, family members or other caregivers, and the broader community but also facilitates the individual's successful transition to adult medical care and active participation in maintaining his or her own health.

## AN ALGORITHM TO GUIDE TRANSITION

Figure 66-1 and Figure 66-2 show an algorithm that specifies the protocol for managing the transition process, assists providers in implementing the transition process, and provides a transition structure for youth and their families. It is intended for use by physicians within a medical home setting as a starting point for identifying youth who have reached a time in their lives in which health care transition should be integrated as a routine part of the office visit. Individual steps along the transition process will vary from one youth to the next depending on individual patient, family or caregivers, pediatrician, and community-resource factors. Discussion of the transition process is best introduced to a patient and his or her parents by the time a child is roughly 12 years of age

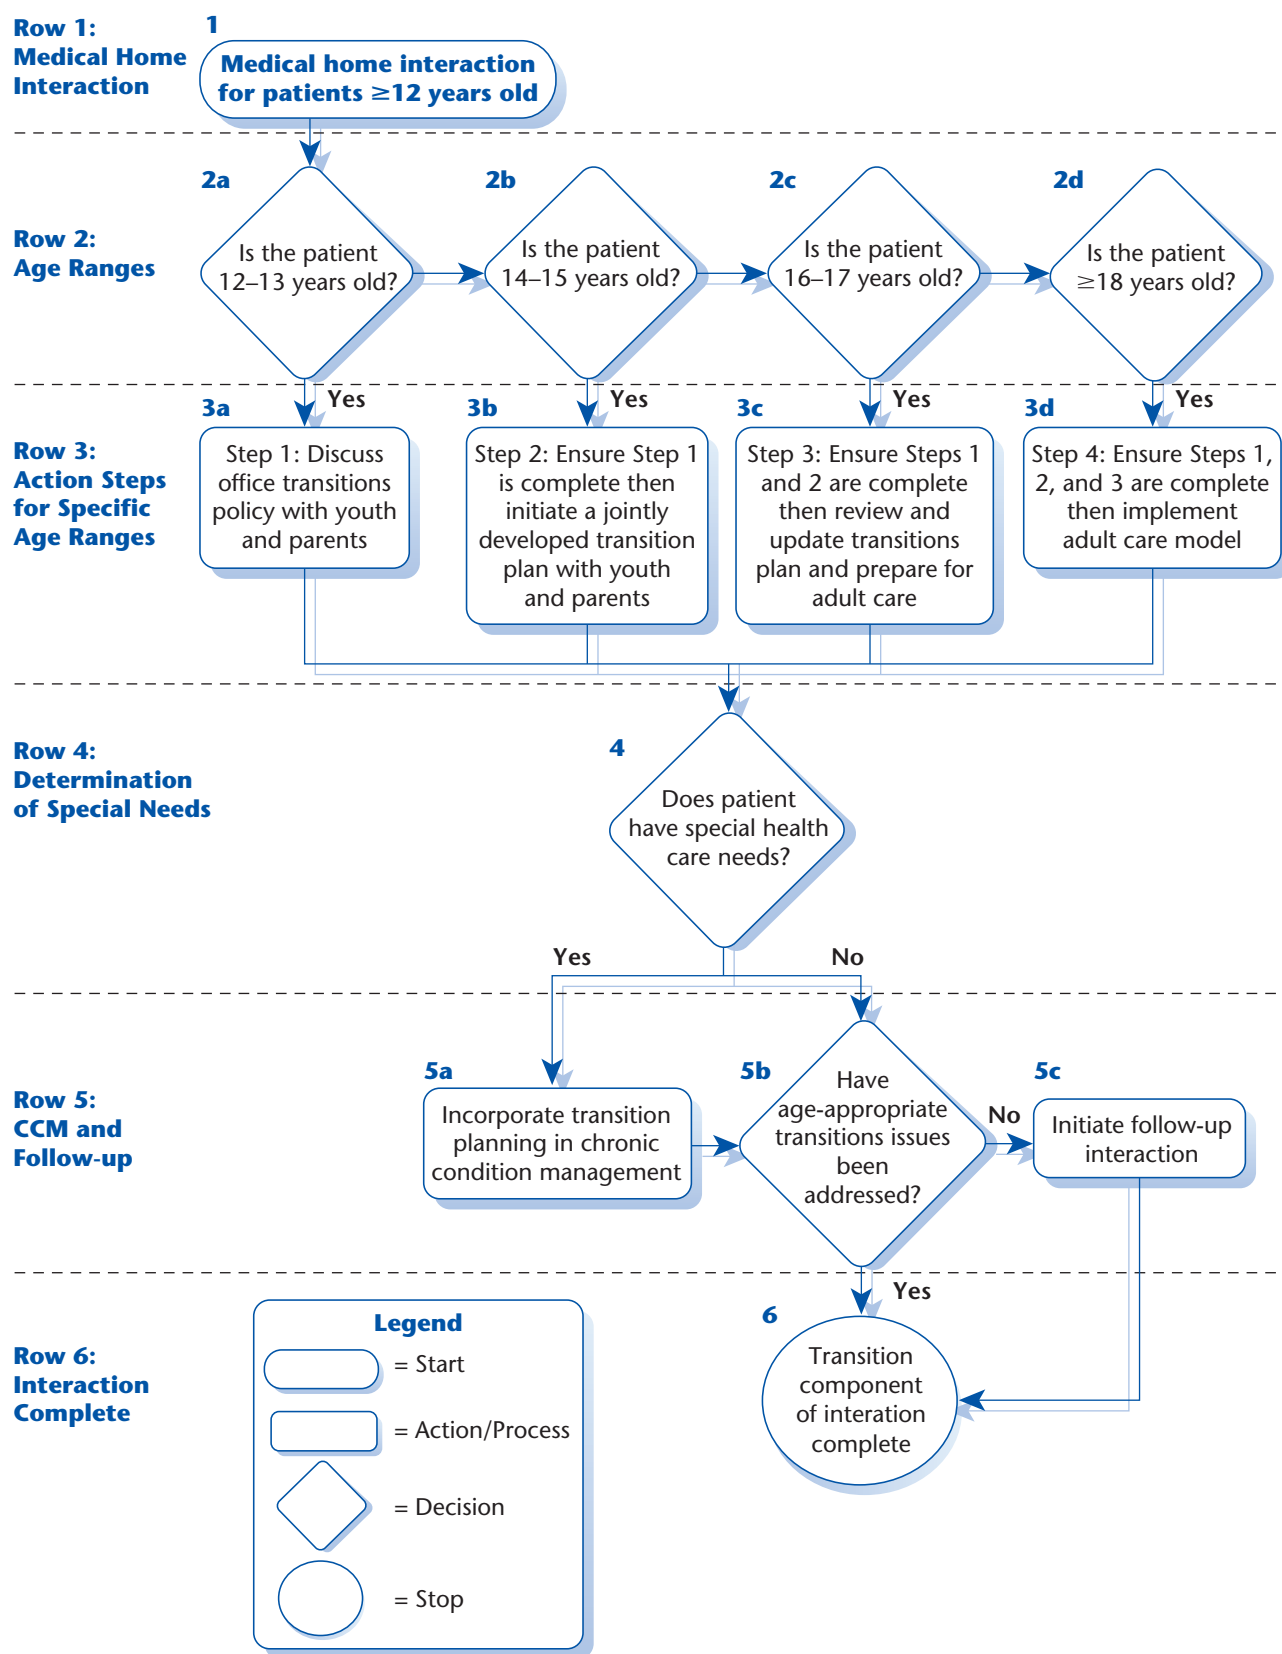

(corresponding to “middle school” development) and ideally should occur during a health maintenance or a chronic care management visit. The AAP clinical report authoring group thought this age was especially important for children with special health care needs and that children without chronic medical issues could wait until 14 years of age (corresponding to “high school” development) to begin the transition process. Transfer itself should typically occur within the 18- to 21-year age range, although it can occur earlier because some internists accept new patients at 15 years of age, particularly if they see other family members as well. Some youth may experience a variety of health care settings as they move from pediatric to adult models of care—for example, while in college or military service—but these settings are not likely to provide a comprehensive medical home. Youth should either remain in their pediatric medical home or be well established in their adult medical home while receiving episodic care in these settings.

Every youth who reaches the age of transition from a pediatric medical home or becomes a legal adult within his or her current medical home needs to have a basic transition plan developed through collaboration among the youth, family, and physician. Those with special health care needs require additional components specifically to address their chronic care management and often in conjunction with school staff.

## TRANSITION PLAN COMPONENTS FOR EVERY CHILD AND YOUTH

There are 4 recommended components for a transition plan, each of which can be augmented by the use of specific tools to facilitate the work of the physician, youth, and family (Box 66-2).

1. **Assess for transition readiness.** The physician, family, school staff, and youth begin by articulating realistic goals for transition and identifying new skills that will be needed by the patient to meet those goals successfully. Although it is not the main focus of the medical home, the readiness assessment should be “person centered” and include identification of other areas of readiness for transition into the adult world in general, including education or vocation, independent living, and patient awareness of medical needs and age-appropriate preventive care, as outlined by such resources as *Bright Futures*. Numerous tools are available in the form of “readiness checklists” that allow providers to obtain a baseline idea of the current capacity of the youth, family, and providers to successfully achieve the outlined goals. Transition progress should be measured through periodic reassessment using the same checklists at each visit. (See Tools for Practice for selected transition-readiness materials.)
2. **Plan a dynamic and longitudinal process to accomplish realistic goals.** The first step of transition planning is the establishing goals that allow the youth to achieve as seamless a transition as possible. A formal transition plan, written in partnership with the youth and outlining specific actions that are necessary to meet the stated goals, should be part of

**Figure 66-1** Transitions algorithm. (From American Academy of Pediatrics, American Academy of Family Physicians, American College of Physicians-American Society of Internal Medicine. Clinical report—supporting the health care transition from adolescence to adulthood in the medical home. *Pediatrics*. 2011;128:1–20.)

ALGORITHM COMPONENT	DESCRIPTIVE TEXT
<b>Medical home interaction for patients <math>\geq 12</math> years old</b>	<b>1.</b> Initiate first step in the health care transition planning process at age 12.
	<b>2a, 2b, 2c, 2d. Age Ranges.</b> By age 12, conduct surveillance to assess any special health care needs. Start actual transition planning by age 14. By ages 16–17, transition planning should be well established. At age 18, initiate an adult model of care for most youth, even if there is no transfer of care. If transition planning does not occur on the schedule described by the algorithm, a concentrated effort is required (eg, special visits) to complete the process successfully.
<b>Step 1:</b> Discuss office transitions policy with youth and parents	<b>3a.</b> Every practice should have a written transition policy that is prominently displayed and discussed with youth and families. The policy should explicitly state the practice's expectations and care process for the health care transition of their adolescent patients to an adult model of care.
<b>Step 2:</b> Ensure Step 1 is complete then initiate a jointly developed transition plan with youth and parents	<b>3b.</b> The practice should use a standard transition plan that can be adapted for each patient's needs. This tool should include components to obtain an accurate assessment of the patient's ability to transition successfully. Providers should interview youth and family members to identify needs and assess the intentions and motivations for youth independence.
<b>Step 3:</b> Ensure Steps 1 and 2 are complete then review and update transitions plan and prepare for adult care	<b>3c.</b> Transition plans must be reviewed regularly and updated as necessary. The provider must also perform surveillance for changes in the youth's medical status and address youth and family concerns that may warrant changes in transition goals. Failure to achieve transition-readiness goals warrants reevaluation of the existing plan and increased frequency of medical home interventions/visits. A "pretransfer" visit to the adult medical home could be conducted during the year before the transfer.
<b>Step 4:</b> Ensure Steps 1, 2, and 3 are complete then implement adult care model <sup>a</sup>	<b>3d.</b> Transition to an adult model of care occurs appropriate for youth's developmental level, which is followed as appropriate by transfer to an adult medical home. Complete medical records should be delivered to the adult provider, along with a portable summary, which is also provided to the patient or guardian. For children and youth with special health care needs, direct communication between pediatric and adult providers is essential, because adult medical personnel may be unfamiliar with certain pediatric conditions.

**Figure 66-2** Algorithm descriptors. (From American Academy of Pediatrics, American Academy of Family Physicians, American College of Physicians-American Society of Internal Medicine. Clinical report—supporting the health care transition from adolescence to adulthood in the medical home. Pediatrics. 2011;128:1–20.)

ALGORITHM COMPONENT	DESCRIPTIVE TEXT
 <p>Does patient have special health care needs?</p>	<p><b>4.</b> Transition planning for children and youth with special needs should include specific chronic care management (CCM) activities such as use of registries; care plans; care coordination; CCM office visits; and comanagement with medical subspecialists. Transition goals must be individualized to account for variations in the complexity of a youth's condition and in the youth's intellectual ability and guardianship status.</p>
 <p>Incorporate transition planning in chronic condition management</p>	<p><b>5a.</b> Youth with special health care needs requires an expanded transition-planning process. Transition planning in CCM includes addressing the exchange of complex health information; competencies for self-care; transfers of specialty care; and issues related to insurance entitlements, guardianship, and eligibility for adult services. In a medical home, such youth may have a written care plan as part of the medical record. At age 14, this plan should include a section titled "transition plan," which should be expanded and developed as the youth approaches age 18 and beyond.</p>
 <p>Have age-appropriate transitions issues been addressed?</p>	<p><b>5b.</b> Use of transition-planning tools and readiness checklists facilitate the provider's ability to ensure that all age-appropriate transition issues have been addressed. Each action step must be completed in order, even if it means the provider has to schedule specific visits to initiate and complete steps missed earlier in the process to catch up before the next visit.</p>
 <p>Initiate follow-up interaction</p>	<p><b>5c.</b> Focused tasks involving little detail or complexity can be addressed by the medical home care coordinator, medical provider, or other appropriate staff through telephone or electronic media. More complex issues may necessitate face-to-face office visits.</p>
 <p>Transition component of interaction complete</p>	<p><b>6.</b> The provider is finished with the transition tasks for that specific interaction or visit; transition planning is an ongoing activity that occurs at every interaction.</p>

Figure 66-2, cont'd

the patient's medical record by age 14 years. The written transition plan should account for cultural, developmental, organizational, and contingency-related concerns. These last would arise specifically out of the child's individual health care needs, requiring plans and processes to address any "contingency" that may develop for that individual. In general, recommended categories within the transition plan include the plan's main goals; identification of whom, within the medical home, will be responsible for overseeing or coordinating the plan;

the timeline for accomplishing stated goals; the skills required by the youth to achieve maximum self-management; the family or other caregivers' role; and proposed financing of the youth's adult health care.

3. *Implement* the plan through education of all involved parties and empowerment of the youth in areas of self-care. After the transition plan has been outlined and goals have been established, specific activities should be initiated to ensure the youth acquires needed skills: for instance, scheduling

**BOX 66-2 Transition Plan Components**

- Assess for transition readiness.
- Plan a longitudinal process to accomplish realistic goals.
- Implement the plan through education of youth, family, and medical providers.
- Document progress to facilitate ongoing reassessment.

one's own medical appointments, obtaining medications, having a one-on-one dialogue with a physician, and being familiar with one's medical history and any needed medications. Ongoing discussion of the transition plan at all health care visits is a key step in accomplishing transition goals. This should be a dynamic process that begins gradually and is assessed at regular intervals. The timing of these reassessments depends on the capacity of the youth, the youth's family and other caregivers, and the amount of time remaining until the anticipated transfer of care to the adult medical home. The transition readiness checklists used during the initial assessment are the tools of choice to document accomplishment of specific goals and tasks. It is highly recommended that a medical home use the same checklists throughout an individual patient's entire transition process to provide continuity over time and assist youth, families, school staff, and providers to remain on track regarding specific goals that have yet to be accomplished. School staff can assist youth with acquiring needed skills. Throughout this process, the physician should continually strengthen the partnership with the patient, the family members, and other caregivers by engaging in active dialogue and information sharing, empowering the youth to take on the appropriate new roles. It is important to recognize that, at the age of maturity, the youth becomes a legal adult (except when guardianship by another person has been obtained). As a result of confidentiality laws, the youth should be seen alone unless other arrangements have been legally made. One to 2 years before the anticipated transfer of medical care, the pediatrician should assist the youth, family, or caregivers in identifying potential adult practices, prepare the appropriate documentation for transition, and suggest that the youth interview the adult practice before making a final transfer.

4. *Document* progress to enable ongoing reassessment and movement of medical information to the receiving physician. Many excellent tools are available to document the transition process, including some that can be used within an electronic health record (EHR) system and others that are paper based. For example, providers might place a transition front sheet on the patient's chart or use a "dashboard" tool in the patient's EHR at age 12 years. Both of these methods work well to flag

**BOX 66-3 Portable Medical Summary Items for All Children and Youth**

- Allergies
- Basic demographics
- Current communication preferences, as applicable (eg, e-mail, cell phone)
- Current medications and alternatives (eg, herbals, complementary and alternative medicine)
- Family history
- Focused screening data as indicated: family history of heart disease, diabetes, associated laboratory tests
- General status: nutrition, physical activity, education, work, living status
- Immunization history
- Social history: independent living arrangements, custodians, emergency contacts
- Medical insurance coverage plan information
- Medical, mental health, and dental providers with contact information
- Medical issues (current) and past medical history with dates: diagnoses, surgeries, imaging studies, laboratory tests
- Risk assessments: smoking, alcohol, substance use, mental health, sexual health, oral health

From American Academy of Pediatrics, American Academy of Family Physicians, and American College of Physicians, Transitions Clinical Report Authoring Group. Supporting the health care transition from adolescence to adulthood in the medical home. *Pediatrics*. 2011;128(1):182–200.

important actions that have occurred or need to be scheduled as part of the transition process. Regardless of the specific tool used, it should provide a flexible method for assessing the youth's readiness for transition and progress made toward that goal. Gathering relevant information to document the patient's transition progress is of paramount importance as the anticipated transfer date approaches. A well-documented barrier to adult medical providers' acceptance of transitioning youth is a lack of accompanying medical documentation. Medical documentation should be portable and include 3 critical components: the transition plan (see earlier), longitudinal readiness checklists (see earlier), and a portable medical summary. The portable medical summary contains basic medical and social data to give adult medical providers the information necessary to begin assuming care for the patient. All youth should help create and receive this portable medical summary because these are essential topics and elements that are critical to transition. Although the categories of the medical summary are appropriate for all chronic health conditions, specific information should be tailored to the individual's conditions. A representative, although not necessarily exclusive, list of items that should be found in the portable medical summary is detailed in Box 66-3 and Box 66-4.

### BOX 66-4 Additional Portable Medical Summary Items for Youth With Special Health Care Needs

- Additional current providers, including subspecialists, therapists, and dental professionals
- Agency providers, including medical supplies, home health agencies, and day services
- Anticipatory disease-related information and planned surgeries
- Care coordinators and case managers, including those from insurance companies
- Communication preferences: literacy levels, preferred language, preferred communication methods
- Condition-related nutritional issues
- Condition-related periodic screening results and recommendations
- Current and planned future assignment of legal decision-making status
- Emergency care plan: actions and contacts in case of emergency and emergency information form
- Enhanced medication history, including preferred means of delivery (eg, liquids only), medications successfully used for flare of condition, previous failed medication trials, and known formulary and authorization issues
- Equipment and device information (including durable medical equipment and implantable devices): contact information for providers, date of receipt, and date of insertion of equipment
- Functional status, including the individual's appearance when content versus stressed or pained
- Laboratory data and other studies (including molecular and genetic testing; past evaluations conducted)
- Nutritional considerations (eg, dietary restrictions, feeding schedules)
- Pertinent test results, including molecular and genetic testing and important radiology results
- Pharmacy phone and fax numbers
- Primary and secondary medical conditions and comorbidities
- Status of prior advance care planning discussions

From American Academy of Pediatrics, American Academy of Family Physicians, and American College of Physicians, Transitions Clinical Report Authoring Group. Supporting the health care transition from adolescence to adulthood in the medical home. *Pediatrics*. 2011;128(1):182–200.

## INTEGRATING TRANSITION PLANNING INTO CHRONIC CONDITION MANAGEMENT FOR CHILDREN AND YOUTH WITH SPECIAL HEALTH CARE NEEDS

Transition planning applies to all children and youth and should follow the steps defined in Figure 66-1 and Figure 66-2. The presence of chronic health conditions or developmental disabilities imposes specific primary

### BOX 66-5 Five Tenets of Chronic Care Management Within the Medical Home

- Registry of youth with special health care needs
- Care plan
- Care coordination
- Chronic care management visits
- Comanagement

care requirements on the family-centered medical home characterized as chronic care management (CCM). Effective CCM, in turn, demands additional considerations related to transition planning. CCM involves an explicit, planned process of coordinated, proactive care aimed at achieving the best possible clinical and functional outcomes for the individual patient and for the population of patients with chronic conditions. While following the general sequence and timing of the transition algorithm, transition planning for children or youth with special health care needs will usually be incorporated into the broader CCM process. Early in the transition planning process, it is important to determine whether or not the youth is likely to be a completely independent decision maker as an adult or require decision-making support from a third-party proxy, such as through guardianship or power of attorney. Even with these considerations in mind, it is important to plan with the youth and family or caregivers to achieve the maximum possible participation of the youth in the transition planning process (Box 66-5).

1. **Registry:** The family-centered medical home CCM process may include a registry of the practice's patients with special health care needs. The registry should be searchable on the basis of patient age so that youth who are ready for each stage of the transition process (see algorithm) can be identified. The registry might also include fields indicating which steps in the transition process are due for completion, have been completed, or are past due for completion. Additional fields unique to the transition of children or youth with special health care needs might include "discussed guardianship" or "identified adult specialists."
2. **Care plan:** Some children or youth with special health care needs will have an action-oriented care plan for tracking current problems and health-related needs, including what action is needed, who will be responsible, and by when the action should have occurred. When a child or youth with special health care needs enters the age group covered in the transition algorithm, the action-oriented care plan should add a transition section that becomes the youth's transition plan. The incorporation of the transition plan into the general action-oriented care plan assists the integration of transition planning with other health-related actions.
3. **Care coordination:** One of the foundations of the family-centered medical home, care coordination

assumes special importance for children or youth with special health care needs who use the health care system frequently and may have multiple service providers. The coordination of health care for the child or youth with special health care needs should take into consideration the youth's transition plan and the current stage of the transition planning process. Care coordination may be instrumental in supporting the transfer of care from various pediatric medical subspecialists to their adult specialty counterparts.

4. *Chronic care management visits:* The family-centered medical home provides periodic CCM visits that may occur in addition to health maintenance and acute illness management visits to monitor the status of patients with chronic conditions and implement or update their care plans. These CCM visits provide occasions for transition education and planning.
5. *Comanagement:* Explicit comanagement between primary care physicians and specialists (medical and mental health) ensures communication and prevents omissions and redundancies of care. It explicitly identifies the respective roles of the primary care medical home and the subspecialists in a manner that is clear to each physician, to the youth, and to the family and other caregivers, including those at school. The locus of management may shift from time to time between primary care and specialty care depending on the youth's age and on the complexity and acuity of specific health problems. Comanagement with subspecialists assumes particular importance in transition planning because it provides the framework in which to plan for and implement the transfer of care from pediatric subspecialists to adult medical subspecialists, surgical specialists, and mental health specialists. Comanagement may also be the context for a dialogue of explicit communications between the youth's pediatric medical home and future adult medical home physician. Comanagement planning with respect to transition planning should include the timing and process for specific transfers of care in each relevant specialty area. In some cases, the plan may be to retain a pediatric subspecialist into adulthood because of the absence of appropriately qualified adult medical subspecialists. Some diagnosis-specific programs, including clinics for hemophilia and cystic fibrosis, have established strong programs to guide subspecialty transfer. The National Hemophilia Foundation established a nationwide network of hemophilia diagnostic and treatment centers and, in 2003, adopted transition guidelines that provide age-related recommendations. These models and transition guidelines acknowledge that there are continuing areas for improvement such as addressing preventive health needs or promoting the adult model of decision-making by young adult patients.

## ROLE OF THE ADULT MEDICAL HOME AS RECEIVING PROVIDER

The transition of a young adult makes it necessary to identify an adult practice that is prepared to accept the patient and provide the full range of care and care

coordination in an appropriate, patient-centered care model. Most young adults are healthy and require only the continuation of health maintenance and promotion and the availability of an adult medical home when acute illnesses arise. Yet even the population of young adults without special health care needs includes those with adolescent-type risky behaviors, mental health and substance use issues, and reproductive health needs that require enhanced attention. Young adults with disabilities and chronic medical and mental health conditions are more vulnerable to failures in the transition of health care services and require more attention from providers and the health care system. Fundamentally, *clinical hurdles* and *process hurdles* present major challenges for a successful move to adult-oriented care for young adults with special health care needs.

Shortages in the adult medical home workforce may limit future capacity to accommodate this diverse patient population. Thus *clinical hurdles* largely encompass deficits in education or experience of some physicians to effectively care for patients with special health care needs, as well as financial disincentives that limit access to adult-oriented care. Reviews of the perspectives of physicians participating in the medical transition of young adults with special health care needs found that, when physicians were exposed to the process of transitioning young adults in the context of their residency training experiences, they were much more likely to incorporate it into their practices following residency. Anecdotally, however, these residency training experiences are not common, and many practicing physicians have learned on the job to manage patients with complex needs. A recent survey of internists' needs when accepting a transitioning youth reported that education in congenital and childhood-onset conditions was critical. Additionally, respondents cited the need for identified specialists to help with management decisions. Although physicians have the role of assuming the care and management of these youth, they should not be expected to do so without supports that are more readily available to pediatricians (eg, state Children's Health Insurance Programs [CHIPs], special education services and resources through public school systems, and Social Security benefits for children with specified conditions); yet too often, they are.

Further work is needed to promote an adult model of care that is responsive to the particular needs of all young adults and sensitive to the specific challenges associated with providing high-quality care to young adults with specific chronic conditions (eg, autism, cerebral palsy, intellectual disability, sickle cell disease, mental health disorders). Ideally, the health care payment system would encourage early and ongoing professional relationships with pediatricians in anticipation of transitions and support comanagement with primary care and specialty pediatricians while the patient is becoming established with the adult practice. At some point, the responsibility for the transitioning young adult will come to rest with the physician, at which time the physician and clinical team should assume a key role in supporting the young adult and his or her family in finding a new balance in

the adult medical setting. The transitioning youth's developmental and functional abilities may influence the transition's success. The continued involvement of the family or caregivers, and school staff as appropriate, should be encouraged during this transition period. Working with the family, caregivers, and other supports to ensure adequate health care insurance and financing for these youth is another major goal of transition.

*Process hurdles* include challenges in the communication of appropriate medical records; lack of adult-focused state, regional, and local resources to provide adults with disabilities; preparation of the young adult and his or her family or caregivers to integrate into an adult-focused medical system; issues related to payment (some addressed by provisions of the Patient Protection and Affordable Care Act of 2010); and young adults' lack of knowledge about health insurance. Adult providers should not expect a "handoff" from pediatric practices but rather a "handshake." Establishing collegial relationships between pediatric and adult medical providers facilitates ongoing access to medical care for patients in transition. Although every transition is different, the best transitions include several core elements. Receivers (the adult medical home team) may reasonably expect that they will be provided with concise and accurate medical information about the youth and his or her condition, as described previously. In addition, receivers should ensure the following:

- The responsible party for medical decision-making has been clearly identified.
- Unambiguous adult consent and confidentiality policies have been explained to the patient and his or her family and other caregivers.
- Communication has occurred about how the practice operates for issues such as paperwork and medication refills.
- Access to the practice for routine and after-hours care has been discussed with the patient and his or her family and other caregivers.

Although many young adult patients transition to adult practices from pediatric-based practices, the unique relationship that many family physicians have with their patients allows for ongoing care throughout the life span. Even though transfer of care may not occur in these situations, it is likely that young adults with special health care needs have pediatric specialists who may wish to facilitate transfer to their adult counterparts. The family physician has the special responsibility to be aware of these needs and, in some situations, play the role of both the "sender" and "receiver."

Certainly, successful transition is a test of the degree to which a practice operates within the ideals encompassed in the medical home model of care. A team approach to the challenges of transition is necessary to facilitate the level of care for which adult providers strive. Inclusion of local public health and community-based resources should be considered wherever possible to ensure that the medical home approach is followed, particularly for vulnerable patient populations with special health care needs.

## GOT TRANSITION: AN IMPORTANT RESOURCE FOR PHYSICIANS

Established in 2010 through a cooperative agreement between the US Maternal and Child Health Bureau/Health Resources and Services Administration and the Center for Medical Home Improvement (CMHI) at Crotched Mountain Foundation, *Got Transition* is the National Health Care Transition Center, focusing on the implementation and dissemination of health care transition best practices in primary care medical homes and specialty settings. This center has become the national resource for health care professionals, families, youth, and state policymakers whose effort focuses on transitioning youth to adult medical homes. Information for medical providers, youth, families, and other stakeholders, including resources for establishing transition plans, portable medical summaries, and ongoing research in the field of transitioning, can be found at [www.gottransition.org](http://www.gottransition.org).

## SUMMARY

A well-timed, well-planned, and well-executed transition from child- to adult-oriented health care, ideally occurring between the ages of 18 and 21 years, enables youth to optimize their ability to assume adult roles and activities. For this reason, transition planning should be a standard part of providing care for all youth and young adults, and every patient should have an individualized transition plan, regardless of his or her specific health care needs. A series of consensus activities has emerged, designed to ensure that uninterrupted, high-quality, and developmentally appropriate health care services are available to patients moving from adolescence to adulthood. This chapter provides a clear timeline, beginning at 12 years of age, to assist providers in implementing transition's 4 specific activities: discussion of medical home transition policy, initiation of transition plan, review and update of the transition plan, and implementation of an adult care model. The Health Care Transition Planning Algorithm from the 2011 AAP clinical report specifies the protocol for managing the transition process, helps providers implement the transition process, and provides a transition structure for patients and their families. The algorithm includes a branch with expanded, generic guidelines for transitioning youth with special health care needs who require chronic condition management. Primary care providers and specialists are encouraged to make this process specific for their own needs and those of their patients.

## Chapter 67

## PALLIATIVE, END-OF-LIFE, AND BEREAVEMENT CARE

Alexander L. Okun, MD

*Most physicians caring for children have not pursued the study of handling death as diligently as they have pursued the treatment of the diseases which cause it.*

VERNICK AND KARON (1965)

This observation remains as true today as it was 50 years ago when it appeared in the sentinel paper, “Who’s Afraid of Death on a Leukemia Ward?” Yet in the intervening half century, the world of pediatrics

has experienced the birth, growth, and development of the field known as palliative and hospice care. In 1997, the Institute of Medicine (IOM) produced the landmark report, *Approaching Death: Improving Care at the End of Life*, followed in 2003 by *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families*, which focused on children with life span-limiting conditions and their families. Progress in the interim is reviewed in the 2014 IOM report, *Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life*.

Along with a collection of outstanding textbooks published in the past 15 years, influential research and guidance that form the basis for this chapter have emerged from the pediatric subspecialty fields of oncology, emergency medicine, pulmonology, critical care, palliative and hospice medicine, and neonatology. Specific citations to a list of references can be found in the online version of this chapter. For information on neonatal palliative and hospice care and bereavement, the reader is referred to Chapter 117, *Support for Families Whose Infant Is Sick or Dying*.

The American Academy of Pediatrics (AAP) calls for ensuring that “all clinicians can provide basic palliative care” and are “trained in basic approaches to prevent, assess and manage symptoms and to communicate in a clear, caring and collaborative manner with patients and families.” This chapter is aimed at general pediatricians and subspecialists seeking to acquire the knowledge and skills needed to do just that. The greatest emphasis is placed on what has recently been learned from empirical studies on the experiences of children with life span-limiting conditions and their families; what these children and families say are the most helpful things pediatricians and other health professionals can do for them; and ways that pediatricians can provide that help.

Throughout this chapter, the term *pediatrician* will be used to refer to the pediatrician, general practitioner, family physician, nurse practitioner, physician assistant, or other health professional acting as the primary care, subspecialty care, outpatient, or inpatient care provider or practitioner. The term *caregiver* will be used to refer to the child’s parents or family members providing the bulk of care. The terms *family* and *families* will be used to refer to the larger collection of those closely related to the child and caregivers, together regarded by the National Hospice and Palliative Care Organization as the “unit of care.”

### DEFINITION OF TERMS

Contemporary practice of *palliative care* embraces a broad scope of services from a point early in the illness, ideally close to the time of diagnosis of a life span-limiting condition. As described by the IOM in 2003, pediatric palliative care seeks to “prevent or relieve the physical and emotional distress produced by a life-threatening medical condition or its treatment; help patients with such conditions and their families live as normally as possible; and provide them with timely and accurate information and support in decision making.” The World Health Organization

(WHO) defines palliative care for children as “the active total care of the child’s body, mind and spirit, and also involves giving support to the family.”

Since the late 1990s, the WHO has advised that palliative care be delivered as an integrative approach to curative care, alongside it, rather than instead of it. The AAP recommends that pediatric palliative care and pediatric hospice care be “provided as integrated multimodal care,” “including cure-seeking, life-prolonging (when in the child’s best interest), comfort-enhancing, and quality-of-life enriching modes of care, along with psychological, spiritual and social support for the family.” Still commonly misunderstood to pertain only to the care of persons who are dying, palliative care is an approach to care that is appropriate for all persons with serious, chronic, life span-limiting conditions.

*End-of-life care* is a type of palliative care that is focused on more intensive assessment and control of symptoms, maintenance of comfort, and psychological and spiritual support in the period before an anticipated death. This period may be brief, as in hours or days, or more prolonged, weeks to months. The duration of end-of-life care among children with chronic neurologic illnesses is longer and less predictable than among those with cancer. Its orientation and organization share many features of palliative care, but it is intended, in the words of Feudtner and colleagues in a 2014 IOM report, for children whose “illness, injury or condition progresses to the point where the health status . . . is diminished below a level that would make it possible to live with . . . meaningful or acceptable quality of life.” In most cases, palliative care interventions should have been implemented long before this stage has been reached. In a 10-year retrospective study using a database capturing pediatric hospitalizations, among more than 24,000 children who died following a hospitalizations of 5 days or longer, the receipt of palliative care services was associated with shorter hospital stays, fewer interventions, and fewer admissions to and deaths in the critical care unit.

Several sets of guidelines and practice recommendations have been promoted by national and international organizations. Some are listed in Box 67-1.

The term *hospice* refers to a combined philosophy of care, program of care, and site of care (the child’s home, hospital room, or an independent facility devoted to care for patients in the last stages of life). In the United States, hospice most commonly refers to a set of services delivered by organizations approved by Medicare, in the home or inpatient settings.

Hospice care shares the priorities of end-of-life care but in the past was restricted to persons willing to forgo life-sustaining interventions or treatments. The Concurrent Care for Children requirement of the Patient Protection and Affordable Care Act of 2010 eliminated the requirement that children with life span-limiting conditions who were insured by Medicaid or the state Child Health Insurance Plans forgo curative or life-prolonging medical treatment to receive hospice care. This advance requires extensive work on the part of pediatricians and collaborating team members to coordinate and

### BOX 67-1 Some Guidelines and Practice Recommendations for Pediatric Palliative and End-of-Life Care

- American Academy of Pediatrics Section on Hospital Medicine and Committee on Hospital Care. Pediatric palliative care and hospice care commitments, guidelines and recommendations. *Pediatrics*. 2013;132:966–972
- NHPCO 2009: National Hospice and Palliative Care Organization. *Standards of practice for pediatric palliative care and hospice*. Alexandria, VA: NHPCO; 2009

- National Cancer Institute. 2014. *Pediatric supportive care for health professionals (PDQ)*. ([www.cancer.gov/types/childhood-cancers/pediatric-care-hp-pdq](http://www.cancer.gov/types/childhood-cancers/pediatric-care-hp-pdq))

ensure coverage for the array of services often needed in the home toward the end of a child’s life.

Although dying at home is widely preferred by adults in hospice, children’s and families’ preferred place of death may or may not be the home. With meticulous advance planning for symptom assessment and management, transfer home can be arranged for children who are assisted by practically any technology, short of extracorporeal membrane oxygenators, even with the intent of discontinuation a short while after transfer.

*Grief* comprises a collection of feelings and sensations, among the most powerful in life, resulting from loss. When these begin before an expected loss, it is referred to as *anticipatory grief*. *Bereavement* is a process that continues lifelong after the loss, beginning with *mourning*, in which the loss is incorporated into the lives of those who survive. Grief and bereavement are further explored later in this chapter.

## CHILDREN INVOLVED

Depending on the degree of involvement in the care of children with complex chronic conditions, a primary care pediatrician based in a resource-rich country might work with children with life span-limiting conditions and their families as seldom as once or twice every 10 years or as often as once or twice a month. Pediatric subspecialists would be expected to be involved much more frequently.

Each year in the United States, roughly 45,000 children die. Just over half of these deaths occur during the first year of life. Two-thirds of infant deaths (those before the child’s first birthday) occur during the first 28 days of life (birth to 27 days); nearly half of these deaths occur during the first hour or day of life. At any given time in the United States, a similar number of children, about 45,000, are estimated to have life span-limiting conditions. Following guidance of the IOM,

WHO, National Hospice and Palliative Care Organization, National Cancer Institute, and Children's Oncology Group and Association of Pediatric Hematology and Oncology Nurses, the principles of palliative care presented in this chapter should be incorporated into the treatment of all these children.

### Childhood Deaths

In resource-rich countries like the United States and United Kingdom, accidents, congenital malformations, and malignancy are the primary causes of death after the first year of life. After accidents, assault and suicide are the second and third most common causes of death among adolescents. Cause-specific death rates for African American children remain as much as 1.5 to 3 times higher than those for white children in most 5-year age groups for conditions originating in the perinatal period, congenital anomalies, accidents, and the category classified as "all other causes."

Childhood deaths in low-resource countries and developing regions are more common and have different causes compared with those in resource-rich countries. Although mortality rates in children younger than 5 years of age have dropped to half of 1990 levels, as calculated by Liu and colleagues in 2012, more than 6 million children still die each year worldwide. More than 98% of these deaths occur in developing regions. Globally, 44% of deaths among children younger than 5 years occur in the first month of life, principally caused by prematurity, birth asphyxia, and infection. Pneumonia, diarrhea, malaria, and congenital anomalies account for most deaths between 1 month and 5 years of age.

### Children With Life Span–Limiting Conditions

Beyond those described previously, children living with a broad range of illnesses, prognoses, and potentials for cure are considered to have life span–limiting conditions. Incorporating principles of palliative care is appropriate for them throughout the illness trajectory, not just at the end of life. Together for Short Lives, formerly the Association for Children's Palliative Care in the United Kingdom, and the National Hospice and Palliative Care Organization in the United States endorse 4 classes of life span–limiting conditions originally described by Goldman, affecting children whose treatment should incorporate the principles of palliative care discussed in this chapter: (1) diseases such as cancer, in which attempts at cure may fail; (2) diseases that will result in premature death, but for which life-extending treatments may prolong life with good quality, such as cystic fibrosis and human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS); (3) progressive diseases for which treatment can only be palliative, such as the muscular dystrophies, mitochondrial disorders, and other neurodegenerative conditions; and (4) conditions with substantial static neurologic disability that results in vulnerability that may result in death, such as severe cerebral palsy.

A conceptualization called *pediatric complex chronic conditions*, developed in 2000 by Feudtner and colleagues, harmonizes with this traditional

classification of life-limiting conditions. These are conditions likely to last 6 months or longer in children who require care by pediatric subspecialists and often a period of hospital care. Many are complications stemming from prematurity or are congenital conditions, cardiovascular or neurologic conditions, or malignancies.

### Children Receiving Palliative and End-of-Life Care

In a 10-year retrospective study reported in 2013 by Keele and colleagues, of more than 24,000 pediatric in-hospital deaths in more than 40 children's hospitals, close to 10% of children receiving palliative care consultation had primary neurologic conditions, and 5% had hematologic malignancies. Feudtner and colleagues reported in 2011 that among children receiving palliative care services in 6 US children's hospitals in 2008, 40% had neuromuscular conditions, 20% had cancer, and 13% had primary lung disease. Half were assisted by technologies such as feeding tubes (most commonly), central venous lines, tracheotomies, and mechanical ventilation. Only one-third of this cohort died in the 12 months that followed the survey. The most common impairments and symptoms experienced by these children included differences in cognition and speech, fatigue, sleep disturbance, difficulty eating and drinking, seizures, pain, and shortness of breath. Across Canada since 2000, children with progressive, noncurable neurologic conditions make up half the children who die each year as described by Steele and colleagues in 2014. The most common symptoms reported by their caregivers were sleep problems; pain and feeding difficulties, with many experiencing constipation; respiratory difficulties; and alterations of alertness or interactions with caregivers.

In lower resource countries and developing regions, where out-of-pocket payments are required for cancer treatment for children, palliative care is seldom provided because of the scarcity of professional resources. The limited availability of opioids contributes to the estimate by Delgado and colleagues in 2010 that 80% of the 250,000 children diagnosed with cancer each year worldwide die without even rudimentary treatment or pain relief.

## COMPONENTS OF BASIC PEDIATRIC PALLIATIVE AND END-OF-LIFE CARE

Palliative and end-of-life care share with curative care a focus on quality of life for the child. They strive to maximize physical and emotional comfort, enable as normal a life as possible for the child and family, facilitate optimal family function, respect and support the child's and the family's cultural and spiritual values, and, in the care of children who are not expected to survive, help the child and family prepare for the child's death (Box 67-2).

Understanding *quality of life* is central to weighing benefits and burdens of proposed therapies toward deriving consensus about which choices for treatment are most likely to promote a child's best interests. Soliciting the child's own assessment of her quality of life, when possible, is strongly urged. Quality of life

### BOX 67-2 Components of Basic Pediatric Palliative and End-of-Life Care

#### PALLIATIVE CARE

- Information and support with decision making
- Thorough assessment, treatment, and monitoring of pain and other symptoms experienced by the child
- Appraisal and reassessment of the child's quality of life, ideally from the child's perspective together with that of the caregivers
- Help for children and caregivers with practical needs
- Psychosocial support and counseling for children and their families
- Attendance to the child's and family's spiritual and religious needs
- Planning for the site of ongoing and future care
- Regular reassessment of care plans based on discussion of the goals of care
- Referral to expert-level pediatric palliative care, as needed
- Ensurance of smooth transitions across the continuum of care, between inpatient and outpatient settings, between primary and specialty care, and at all stages of the child's life

#### END-OF-LIFE CARE

All of the components of palliative care, *plus*

- More intensive assessment of the child's physical well-being and the child's and caregivers' emotional, social, and spiritual needs
- More focused support in advance care planning, including help anticipating the nature and site of death
- Information about and support through the dying process
- Access to advice on symptom management and comfort and care coordination 24/7
- In the United States, referral to hospice services if the child's condition, following a typical course, could be expected to result in death within 6 months
- Planning for arrangements after death

From Institute of Medicine. *Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life*. Washington, DC: National Academy Press; 2014; adapted from Himelstein BP, Hilden JM, Boldt AM, et al. Pediatric palliative care. *N Engl J Med*. 2004;350:1752–1762.

has been rated higher by children with neuromuscular disabilities, particularly in subjective domains such as emotional and psychosocial well-being, than by their parents, as reviewed by Jardine and colleagues in 2014. Bjornson and McLaughlin showed in 2001 that self-reported quality of life among children with cerebral palsy does not correlate with the degree of spasticity. Pediatricians may appraise quality of life less favorably among hospitalized patients than their families do, as demonstrated in 2014 by Nolan and colleagues.

The life course of many children with life span-limiting conditions changes at critical junctures, some predictable and others surprising, often coinciding with

### BOX 67-3 Opportunities to Discuss the Child's Condition and Prognosis, Quality of Life, and Goals of Care

- Hearing bad news
- Acute decompensation
- Worsening symptoms that are becoming harder to manage
- Increased time spent in the hospital or the critical care unit
- Progression of the disease or condition or its secondary complications
- Recovery from acute decompensation to a lower level of overall function
- When families face decisions about the initiation of new technologies or treatments
- Slow decline preceding death
- When the child and family face decisions about starting a new technology or agreeing to a major invasive procedure
- Any other sustained, significant diminution in the child's quality of life
- End of life

Derived in part from Friebert S, Osenga K. Pediatric palliative care referral criteria. Center to Advance Palliative Care; 2009; and Klick JC, Hauer J. Pediatric palliative care. *Curr Probl Pediatr Adolesc Health Care*. 2010(July):120–151.

encounters that the child and family have with pediatricians and health systems. These visits present opportunities to begin or reopen discussions about the child's overall condition, prognosis, and quality of life; the child's and family's goals for care; and the most likely means to achieve those goals (see Box 67-3).

#### On Teams

Palliative and end-of-life care ideally consists of team-based, multidisciplinary, longitudinal support. More and more, palliative care is being provided in children's hospitals by consult services comprising anywhere from a single pediatrician to a multidisciplinary team of professionals as surveyed by Feudtner and colleagues in 2013. Regarded as the "unit of care," the family is assessed for coping, psychological stressors, sources of support, spiritual needs, and crises in family unity. The roles of team members are complementary, overlapping, and interdependent, as reviewed in several recent publications. These teams may include social workers, chaplains, other spiritual care workers, child life specialists (including expressive arts and music therapists), care managers, bereavement specialists, psychologists, psychiatrists, pharmacists, nurses, physicians, and advance practice nurses.

According to the AAP, child life specialists aim to provide developmentally focused support, promote children's adjustment, reduce their anxieties, diminish their sense of helplessness, and organize peer to peer support. Their well-known expertise in the use of non-pharmacologic techniques around procedures leads to

reduction of children's pain and anxiety. As outlined as well by Sutter and Reid in 2012, they can help caregivers create mementos through photography, art, crafts, and music that may be difficult to collect at emotionally stressful times, but will be treasured later.

Social workers provide emotional and psychosocial support, share resources with families, and assist with referrals to community-based agencies that may enable smooth transitions to care at home or hospice. Their skills and roles overlap with and complement those of others on the team. Chaplains and spiritual care workers play a critical role, together with community-based religious leaders, addressing spiritual and existential crises that may fall outside the boundaries of established religious constructs or the expertise of other members on the care team.

### Advance Care Planning

Since the development and implementation over the past 15 years of adult-oriented advance care plans known as *physician orders for life-sustaining treatment*, or POLST (or, in some states, MOLST, with *medical* substituted for *physician*), methods for soliciting and honoring the values and priorities of children have received increasing attention. In the United Kingdom, *personal resuscitation plans* list individualized details addressing what interventions to provide, the preferred place of death, organ donation, autopsy, care of the body, and funeral or memorial rites. A similar instrument in use in the United Kingdom and New Zealand is called "Child and Family Wishes." These plans frame the child's and family's choices positively, as opposed to more traditional orders "not to" carry out 1 or more interventions, such as *do-not-resuscitate* orders.

In the United States, tools known in the past as "My Thoughts," "My Wishes," and "My Voice" were revised and merged into "Voicing My Choices," available through Aging With Dignity ([www.agingwithdignity.org](http://www.agingwithdignity.org)) for use with children and families. They have been the subject of study among children and young adults with advanced HIV disease and cancer. Considered a "vehicle for information exchange" by the British Thoracic Society in its 2012 guideline for respiratory management of children with neuromuscular weakness, advance care plans permit adolescents and young adults to choose and document the medical treatment they do and do not want, how they want to be cared for, what they want their friends and family to know, and how they want to be remembered. Liberman and colleagues showed in 2014 that basic knowledge about advance care planning remains limited among parents and many pediatricians.

Children's awareness that they are dying becomes more focused and pronounced during the terminal phase of their illness. The British association Together for Short Lives suggests that pediatricians and any member of the health care team ask themselves 4 questions as prompts to junctures when discussions about the wishes of a child and family are appropriate (see Box 67-4).

This organization offers an outstanding guide for families with children with life span-limiting conditions, referenced in the box. The Institute for Health

#### BOX 67-4 Prompts for When Discussions About Advance Care Plans Are Appropriate to Begin or Revisit

The pediatrician and other members of the health care team should ask themselves the following questions:

- Would you be surprised if this child died prematurely because of a life-limiting illness?
- Would you be surprised if this child died within a year?
- Would you be surprised if this child died during this episode of illness care?
- Do you know what the child's and family's wishes are for the end of life?

If the answer to any of these questions is "no," it may be an appropriate time to begin or revisit discussions about advance care plans.

Care Improvement in the United States has published *The Pediatric Starter Kit: Having the Conversation With Your Seriously Ill Child* as a guide to caregivers seeking to initiate discussions about advance care planning.

### ETHICAL ISSUES

The imperative to provide effective and timely palliative and end-of-life care is grounded in pediatricians' fidelity to their patients and obligations to promote the best interests of the child. Attention paid to the principles of palliative care can lessen the risk for iatrogenic harm through vigilance for the adverse effects of polypharmacy and careful consideration of proposed surgical and medical interventions whose benefits and burdens may be unfavorably balanced.

Respecting children's autonomy and that of their caregivers serves as the impetus for collaborative decision making. It creates an obligation, called *veracity*, for the pediatrician to inform children about their health status as fully and sensitively as possible, with respect for each family's culturally rooted and personal health beliefs and practices. The development of tools to facilitate advance care planning and honor the wishes of children and families grew from these obligations.

Decisions about withholding or withdrawing (together called *forgoing*) life-sustaining medical or surgical treatments are best made through examining the balance of potential benefit and harm or distress resulting from the pursuit of each proposed treatment. The interests of family members are also critical and should be considered among the burdens and benefits of treatment choices when examination of the child's best interests does not lead to a clear path of action.

Although withholding and withdrawing specific life-sustaining interventions are considered to be legally and ethically equivalent, they are experienced differently by many health professionals and family members. Pediatricians and caregivers unsure of the benefits of specific interventions near the end of life can plan time-limited trials of these treatments; if, after a suitable period, the burdens of a particular intervention seem to outweigh its benefits, then it can be withdrawn.

As shown by Lee and colleagues in 2010, most deaths in pediatric critical care units are preceded by some limitation of care. As life-sustaining medical treatments are forgone, it may be advisable to have formal orders in place not to attempt resuscitation. In a 2014 study by Burns and colleagues of 133 pediatric deaths across 5 pediatric critical care units in the United States, where 70% of the deaths examined were preceded by withdrawal of life-sustaining medical treatment, one-third did not have formal do-not-resuscitate orders in place at the time of death. The authors raised questions as to the necessity for such formal orders when it was understood that forgoing life-sustaining medical treatment would be followed, in most cases, by death. It has been argued that the common institutional default in US hospitals to provide cardiopulmonary resuscitation unless explicitly precluded by a formal order contributes, in the words of Clark and Dudzinski, to a “culture of dysthanasia,” or prolongation of suffering as death is postponed.

According to the AAP Committee on Bioethics, “it is not ethically mandatory to provide medically administered fluids and nutrition to a child in a permanent vegetative state or other condition that results in a permanent lack of conscious awareness.” Pediatricians need to work to dispel misunderstandings among caregivers and colleagues about any suffering that is thought to be associated with dehydration among children in these states. In a small follow-up study by Rapoport and colleagues in 2013, with families who had limited or discontinued medically provided hydration or nutrition as their children approached death, parent participants reported satisfaction with their decisions but expressed concerns about feeling negatively judged by health professionals. The notion that medically provided nutrition and hydration need to be an “all or nothing” matter can be moderated by an approach that provides small amounts, as tolerated, known as “comfort feeds,” or in the geriatrics literature, “feeding for comfort.”

The forgoing of life-sustaining medical treatment for critically ill or extremely premature newborns has received much legislative attention in the United States. According to the American Medical Association Council on Ethical and Judicial Affairs, “when consensus about what is in the best interest of the child cannot be reached despite reasonable efforts to do so, the wishes of the parent[s] should prevail” unless they “clearly are not committed to serving the child’s interests, are emotionally unstable or lack capacity to make informed decisions.” Hospital ethics committees and community-based ethics consultants can help to clarify the ethical issues pertaining to specific cases and support efforts at mediating

disagreement or conflict between and among professional staff, patients, and caregivers.

Concerns about the future quality of life for children with significant neurodevelopmental disabilities may be influenced by beliefs that caregivers and pediatricians have about the effect these disabilities have to diminish it. Graham and Robinson expressed concern “that many clinicians may unconsciously use the phrase, ‘quality of life’ to mask a set of more complicated, unspoken assumptions about the lives” of children and youth with disabilities. In the care of some children with trisomy 13, trisomy 18, and other combinations of complex congenital anomalies traditionally considered to constitute “lethal conditions,” Koogler, Wilfond, and Ross pointed out that what possibly “make[s] them lethal is the decision not to repair the anomalies or treat the disabilities.” Maintaining a child- and family-centered focus in the appraisal of quality of life is critical to balanced, unbiased discussions of goals of care.

Some treatments intended to relieve pain and suffering may seem to hasten death. Treatment of severe pain with high doses of opioid analgesics often raises concerns about the risk for causing respiratory depression. Even when doses are carefully titrated in response to the patient’s pain, opioids may have a foreseeable and unintended effect to diminish respiratory drive. Under the Principle of Double Effect, the unintended side effect is ethically permissible on the conditions that only the beneficial effect of the treatment (comfort) is intended and that the mechanism by which the intervention relieves suffering (lessening pain) is not the adverse effect itself (respiratory depression that leads to death).

Euthanasia and physician-assisted suicide are not endorsed by any advisory or governing body of physicians treating children in North America, although other countries may permit these measures under certain circumstances. The AAP suggests that requests for euthanasia “should be acknowledged and serve as a starting point of a conversation to elucidate the sources of suffering that underlie such requests.”

## FUNDAMENTALS OF WORK WITH CAREGIVERS, SIBLINGS, AND FAMILIES

To work with families in ways that are most effective and supportive, pediatricians should be knowledgeable about the range of experiences that have been described in empirical research with caregivers, siblings, and families close to children with life span-limiting conditions.

Parents strive to be “good parents” for their children with life span-limiting conditions by providing support, presence, and sacrifice for the child. The work of Hinds and colleagues demonstrates that they make informed, unselfish decisions in the child’s best interests, meet the child’s basic needs, remain at the child’s side, show the child love, try to protect the child’s health and prevent suffering, teach the child moral values, and advocate for the child.

As reported by Rallison and Raffin-Bouchal in 2013, parents of children living with progressive neurodegenerative illness described their “pervasive grief”

from the experience of “living in the in-between,” facing the day-to-day dualities of joy and sorrow, having a sense between illness episodes of both stability and unpredictability, mastering intricate home care regimens and feeling loss of control amid their complexity, and, ultimately, having ambivalent wishes as the child’s death approaches that the child will not die, but be relieved of his suffering.

Siblings experience many unmet needs over the course of the child’s illness. Davies in 1999 described their multifaceted pain, confusion, alienation, and feelings of inadequacy. Siblings may feel “unnoticed or unacknowledged” at hospital visits and other appointments for the child’s care, left out of communication about the child, or “falsely protected” during the child’s deterioration and other critical times, according to the work of Jones and colleagues in 2014. Their privacy may be intruded on as they meet the need to adopt new responsibilities and roles. As Lapwood and Goldman wrote in 2012, they may feel criticized by others when they react with aggression and disruptive behaviors. For many reasons, parents may be unaware of many of these experiences and how challenging the coping process is for siblings.

Children who are dying sometimes worry that they will be forgotten. Many are troubled by imagining their parents’ pain and sadness after they are gone. Some feel preoccupied with their own safety and security. For some older children, as for some adults who face dying, the main goal of living during the terminal stage is, in the words of Nitschke in 2000, to find “new meaning in life and to live in a new mindset.”

For adolescents and young adults as described by Linebarger and colleagues in 2014, crucial developmental tasks related to autonomy, identity formation, and sexual expression, among others, may be thwarted by changes in stamina and appearance and the isolation and confinement to treatment routines imposed on them. Most will have achieved an understanding of the attributes of death—irreversibility, nonfunctionality, universality, and causality—that permit higher level discussions around advance care planning than are possible with younger children.

From a family systems perspective, pediatricians should recognize how the roles of parents, siblings, and other loved ones change over the course of care for a child with a life span-limiting condition. As reviewed by Lapwood and Goldman in 2012, the effectiveness and style with which various family members cope may be different and out of sync. Family members may need and receive different levels and types of external support. One parent or a sibling may feel the need to care for the other parent in addition to the meeting the needs of the child. Pre-existing strains in the marriage, or in relationships between family members and the child who is ill, complicate the calibration of family roles required to care for the child. The normal balance of loyalty, affection, rivalry, and aggression between siblings needs to be reestablished. Resilience among families is promoted by shared belief systems, established patterns of organizing their day-to-day lives, strong communication processes, cohesiveness, flexibility, and expressiveness.

### Spiritual Support

Spiritual needs of children and families involved in palliative, end-of-life, and bereavement care are based in traditional religions, unique religious affiliations and interpretations, and nonreligious paradigms. All give meaning to individuals’ lives. The decline in health of a child can be among the greatest spiritual and existential crises for a parent, yet it is possibly the spiritual domain in which the least training is provided to pediatricians. Addressing children and families’ spiritual needs requires exploration and understanding in domains of professionalism and humanism that are disquieting and profound. Membership in the same religious group or sect as the family or belief in God is not required for professionals to be able to offer spiritual support. Collaboration with the family’s religious leaders or hospital-based chaplains may enrich support.

### Communication Methods That Help

Many physicians feel anxious and inexperienced when initiating talks with caregivers about end-of-life care. They may postpone or defer such discussions because of their own discomfort, lack of training, lack of reimbursement, competing demands, or language barriers. Davies and colleagues showed in 2010 that in some settings, families with limited English proficiency have received no information or only basic information about their child. As shown in a series of studies published between 2008 and 2014 by Davies, Junger, Durall, and their colleagues, pediatricians may hesitate to discuss poor prognosis because of the inherent uncertainty, a belief that the family is not ready to acknowledge that the condition cannot be cured, or concern that doing so will take away hope. In a series of recorded discussions around informed assent to enroll children with advanced cancer in phase I treatment trials, 85% of pediatric oncologists failed to mention that the cancer was incurable, and two-thirds did not offer the option of comfort-oriented end-of-life care as reported by Miller and colleagues in 2014.

In research on discussion of prognosis and preservation of hope among parents of children with cancer, Mack and colleagues in 2007 were able to demonstrate that conversation about poor prognosis was not associated with a loss of hope. Hopeful ways of thinking were associated in a study published by Feudtner and colleagues in 2010 with greater odds of parental assent to limit life-sustaining medical treatment. Hopefulness does not necessarily equate with expectations of cure, but rather with the belief that particular goals can be reached and that the child and family will have some sense of agency in getting there.

In many reports, parents say that they want pediatricians to discuss prognosis in conversations centered on the child and, in the words of Morrison and Meier in 2004, “focused on empathy, openness and reassurance.” We know from work published between 2005 and 2010 by Davies, Mack, Meyer, and their colleagues that they value pediatricians who offer clear, compassionate, informative explanations; tolerate denial and expression of emotion; demonstrate interest in family members; attend to cultural values; work

to preserve the parent-child relationship; remain accessible and committed to follow-up; and prepare the parents for circumstances surrounding the child's death. In conversations about prognosis, wrote Schwantes and O'Brien in 2013, "the goal is not to be brutally honest but to have honest conversations."

Parents told Weidner and colleagues in 2011 that factors that mattered most to them in the course of their children's end-of-life care included respect for the family's role, support for parental decision making, the demonstration of humanistic and compassionate communication, and the provision of comfort, spiritual care, and access to care and resources. Those speaking with Tan and colleagues in 2012 emphasized the presence of a "dependable" person and consistent "witness" to conversations. In a longitudinal study underway with families of children with life span-limiting conditions, Hill and colleagues reported in 2014 that they are investigating ways to best support a process they call "regoaling," in which parents realize that their initial hopes for the child's health trajectory may no longer be realistic and choose to pursue or engage in a new set of goals. At a minimum, families with limited English proficiency told Davies and colleagues in 2010 that they seek "comprehensive information from sensitive providers who respect parents' roles in their child's life."

Although more open communication with children has been generally embraced, conflicts persist about the timing of disclosure to the child that she is dying. In a 2004 follow-up study based in Sweden by Kreicbergs and colleagues of families whose children died of cancer, no parents who discussed the anticipated death with the child who died reported that they regretted doing so, but some who chose not to broach the topic wished they had. Some basic suggestions for facilitating conversations with children and families are listed in Box 67-5.

Parents and siblings have indicated, as reported by Steele and colleagues in 2014, that it is helpful to ask siblings directly about their experience, engage them in care discussions, and provide roles for them in the child's care. They recommend, as described by Lapwood and Goldman, that siblings remain engaged in their usual activities to the greatest extent possible and that at least 1 adult be identified in their world with whom they can talk to openly about their feelings and fears and why their lives have been so disrupted. Portnoy and Stubbs wrote in 2012 that resilience in siblings is promoted by close connections with at least 1 family member and the availability of support systems outside the family. When possible, parents advised that a child life specialist or worker with similar skills be assigned specifically to work with siblings.

Families cite the importance of parent-to-parent support. They can often identify sources through the care team and regional or national organizations, some of which are listed in Box 67-6.

### Common Types of Conversations With Children and Families

Although every conversation with each child and family is unique, there are several categories or types of discussions and meetings that take place frequently.

In interviews with children and families, Kane and colleagues offered suggestions for some "exploratory questions" around the effect on the child and family of the child's condition. These and the suggestions of other authors are reproduced in Box 67-7.

In the words of Block, "A family meeting is a procedure, and it requires no less skill than performing an

#### BOX 67-5 Facilitating Conversations With Children and Families

**General suggestions:** In speaking with children and families, the pediatrician should

- Plan for more than a single conversation over time
- Get a sense of the child's and family's information needs and styles of communication
- Explore the child's and family's hopes and concerns
- Check comprehension frequently
- Tolerate negative emotional responses from caregivers
- Accept differences of opinions between caregivers
- Remain comfortable with nonacceptance and try to identify areas of consensus understanding
- Not be afraid to say that he doesn't know
- Reflect on and manage her own anxieties and fears

**When speaking with children who are ill and their siblings,** to get the best sense of the child's developmental level and understanding of illness or death,

- Ask what they understand
- Ask clarifying questions
- Take cues from the child as to where to bring the conversation next
- Talk in language the child can understand, avoiding euphemisms
- Break information down into very small portions
- Listen more, speak less
- Support the child's voice in decision making and involvement in rituals
- Reassure the child that he is loved and will not be abandoned

**When speaking with caregivers and families,** to help improve the family's quality of life and comfort, ask them

- About effects of the child's condition on his or her abilities
- How various family members are being affected emotionally, socially, and financially
- What they think the siblings know and understand
- What they feel would be most important for the team to know

operation." In the field of communication with patients and families, more tips, acronyms, and 4- to 10-step processes have been developed to guide professionals in giving bad news and holding family meetings than probably any other aspect of communication. Notable examples include "Ask-Tell-Ask," "NURSE," VALUE," "SPIKES," "SEGUE," and "ASCEND." Some basic elements in common are listed in Box 67-8.

### WORKING WITH FAMILIES AROUND THE TIME OF THE CHILD'S DEATH AND DURING BEREAVEMENT

The focus in this chapter has been predominantly on work that pediatricians who have ongoing relationships with families can engage in over time. Johnson and colleagues provide advice for communicating with families after the serious traumatic injury or death of a child, which includes doing interdisciplinary work to collect the facts, enabling communication that is clear and simple, providing time for clarification and the expression of emotion, preparing for parental responses and need for support, helping parents with final decisions and understanding procedures, maintaining contact after the death, and providing

### BOX 67-7 Exploratory Questions to Ask in Interviews With Children and Families About the Effect of the Child's Illness or Condition

#### To start:

- For children with static conditions from birth or early infancy: Tell me about your child on a good day.
- For children with acquired conditions: Tell me about your child before he or she got sick.
- What sorts of things does your child like to do or enjoy?
- What kinds of activities and things are most important for your child to be able to do?
- How does your child communicate with you and let you know what she wants or needs?
- Is your child currently feeling all right? If not, what symptoms are bothering him the most?
- How would you describe your child's quality of life nowadays?

#### Hopes, goals, and priorities:

- What goals are most important to you and your family nowadays?
- As you think back, how do you see your child's health over time (eg, the past month, the past 6 months)?
- As you think about your child's condition, now and in the future, what are you most hoping for?
- What have been the most challenging or frustrating aspects of your child's medical care?

- What makes you feel the most worried, thinking about your child? How often do you find yourself thinking about that?
- Are you comfortable with the health care decisions you have made for your child?

#### Spirituality and supports:

- Do you have a set of beliefs that guides you or supports you? It could be based in religion, or not.
- Does your faith or religion provide any guidance in the decisions you are facing?
- Who provides you with the most support nowadays? Who do you call on or reach out to when you need to talk or need help?

#### Emotional effect:

- How has your child's condition affected her emotionally?
- How has it affected you in your own life?
- How are you coping? How about your spouse, partner, or other loved ones?
- (Alternative: How are you handling everything that's been going on?)
- What worries you the most nowadays?
- (As appropriate: What worries your child the most?)

Throughout, it is preferable to use the child's name in place of "your child."

"Nowadays" may be a term in common use in some settings but not others. Substitutes include "right now," "recently," "these days," and more. "Condition" is one way of referring to what makes the child "unwell." Substitutes include "illness," "medical problems," "situation," "circumstances," and more. In Wolfe J, Hinds PS, Sourkes BM, eds. *Textbook of Interdisciplinary Pediatric Palliative Care*. Philadelphia, PA: Elsevier Saunders; 2011.

### BOX 67-8 Commonalities Across Different Methods and Frameworks for Giving Bad News and Holding Family Meetings

The pediatrician should

- Prepare ahead of time with all the pertinent facts.
- Plan the setting in which the conversation will be held and arrange that all important persons are there for the conversation.
- Get a sense of how much the family and child already know and expect or are prepared to hear.
- Explain what the pediatrician has learned in ways that are effective and compassionate.
- Permit the child and family to respond.
- Address their emotions and solicit questions.
- Plan the next steps, including when the pediatrician will see the child and family next.

information about arrangements for bereavement-associated needs. Similar guidance is formalized in a joint statement from the AAP Committee on Pediatric Emergency Medicine, American College of Emergency Physicians, and the Emergency Nurses Association, which also addresses family presence during attempted resuscitation, continued contact with surviving family members, and ways to provide the most effective communication training for pediatricians.

The pediatrician has an essential role in providing practical and emotional support after death, both on his own and as part of a bereavement team. A pediatrician may wish to go to the wake, funeral, or memorial service for her patient. Families feel moved that their child meant so much to health care professionals in attendance. Many hospitals and hospices organize memorial services or other annual events for children who have died while in care there. Sending notes or calling to acknowledge the child's birthday or anniversary of death, often comforting for the family, can be facilitated by maintaining a calendar of these dates and the organized activities of bereavement teams. Providing psychoeducation about the prolonged nature of grief and referral to bereavement specialists or teams can be helpful.

Surviving siblings who receive care from the same pediatrician will be returning for visits that provide an opportunity for all to remember the child who died.

The pediatrician may want to bring the siblings back into the office soon to assess how the siblings, parents, and extended family are coping.

Death of the child leaves an enormous void and is widely acknowledged as among the most painful losses anyone can experience. As described by Portnoy and Stubbs and by Gaab and colleagues in 2014, the bereaved typically experience overwhelming grief and other feelings, physical sensations, thoughts, social difficulties, and spiritual searching. The death may come as a surprise to siblings who, despite knowing that the child was worsening, did not expect the child to die. Children may demonstrate what Wilkins and Woodgate in 2005 termed “stop-and-start” grieving, called “puddle jumping,” as they seem to be immersed in sadness, despair, loneliness, yearning, disbelief, confusion, guilt, anger, or anxiety one moment and then seem to be playing normally the next. They may experience a sense of worthlessness and pointlessness and resent their parents’ “absorption in their own grief” as depicted by Portnoy and Stubbs.

Just at the times when the greatest degree of support is needed, families lose relationships with home care personnel, pediatricians, and hospital staff who have often been the core source of support. Their self-concept as caregivers and the organization of their daily existence and purpose are gone. As others in families’ lives begin to speak or ask less often about the deceased child or sibling, this creates another loss of support for the bereaved, who might otherwise be helped by opportunities to continue talking about the deceased as a way of keeping the relationship alive.

In contrast to some of the teachings of Freud, Bowlby, Parkes, and others, individuals’ grief experiences often do not follow a stepwise progression through stages and do not end in resolution, “coming to terms,” or closure. Grief continues to be present in the life of the bereaved, described by Roos in 2002, requiring “continual energy and adaptation,” in the words of Rallison and Raffin-Bouchal. Bonds with the deceased continue as the bereaved learn to “hold on while letting go.” Contemporary models of understanding bereavement depict grief as something that doesn’t lessen, but that the bereaved “grow around.” The focus of help is on finding ways the bereaved can incorporate the pain and loss into their daily lives.

Parents who experienced prior losses, economic hardship, psychiatric comorbidity, poorer perception of medical care, and less preparedness for the child’s death, together with those whose children experienced more intense suffering and poorer quality of life, are at risk for worse outcomes of grief, according to a 2012 study by Rosenberg and colleagues. In a follow-up study of bereaved parents published in 2013 by Youngblut and colleagues, 89 hospitalizations among 56 mothers and 9 hospitalizations among 7 fathers were reported in just the first 13 months after the child’s death; up to one-third of these hospitalizations were classified as stress related. Death of a child is associated with a great deal of financial hardship as well, with poor families in a 2011 study by Dussel and colleagues experiencing the greatest financial loss. Some parents find comfort in altruistic engagement,

### BOX 67-9 Advice for Families That May Help Siblings Anticipating Loss or Grieving After Death

- Spend plenty of time with the children.
- Encourage children to express their feelings and thoughts in their own ways.
- Explain what happened, and be prepared to answer questions again and again.
- Appreciate children's understanding of death at different developmental levels.
- Facilitate children's involvement with friends and activities.
- Continue the usual routine of family responsibilities and discipline as a way of "normalizing" life.
- Let children know that adults also feel anger, sadness, and fright and may express it, and that crying is okay.
- Share your own feelings and memories.
- Allow time for fun and laughter.
- Tell children how much the sick or deceased sibling loves or loved them.
- Avoid comparisons between survivors and the deceased.
- Let children know they will be cared for and loved by a consistent adult.

Derived from Davies B, Wordon JR, Orloff SF, et al. Bereavement. In: Carter BS, Levetown M, eds. *Palliative Care for Infants, Children and Adolescents: A Practical Handbook*. Baltimore, MD: Johns Hopkins University Press; 2004; American Academy of Pediatrics, Committee on Psychosocial Aspects of Child and Family Health. The pediatrician and childhood bereavement. *Pediatrics*. 2000;105:445–447; and Davies B. After a child dies: helping the siblings. In: Armstrong-Daily A, Zarbock S, eds. *Hospice Care for Children*. 2nd ed. New York, NY: Oxford University Press, 2001:168.

in giving to others after the child's death, as reported by Tan and colleagues.

Many siblings experience anxiety, depression, and, among older siblings, illicit substance use, particularly in the first year of bereavement. Those who reported dissatisfaction with communication, poor preparation for the sibling's death, or missed opportunities to say goodbye experienced greater distress and less adequate support, as shown by Rosenberg and colleagues. In addition to these intense feelings, the changes in siblings' lives involve numerous losses—less time with parents, diminished tolerance by parents, emotional unavailability, loss of companionship with the sibling who has died, and disintegration of family dynamics. As described in Wilkins' and Woodgate's review, many report gains as well—increased family closeness and cohesion for some, greater independence and maturity, and an enhanced capacity for empathy and desire to help others. Efforts to protect siblings from the pain of the loss and the parents' grief are often ineffective and may worsen short- and even long-term outcomes. Some advice for families that may help siblings anticipating loss or grieving after death is included in Box 67-9.

Bereavement care calls for sustained connection between the pediatrician and the surviving family after the child's death. It begins with acknowledgment

of the child's death and continues through attention to parental grief, stressors that may intensify the grief, and the experiences of surviving siblings. Some pediatricians find that meeting with families several weeks after the child's death brings a sense of closure for them and thus can be helpful in the pediatricians' own self-care.

## SYMPTOM MANAGEMENT

In-depth attention to the assessment and management of pain and other symptoms is central to palliative and end-of-life care. Great suffering is often present, especially in children with cancer, who may experience pain, dyspnea, and other troubling symptoms that are not sufficiently relieved by medications provided. As described earlier, children with severe neurologic impairment and those dying from conditions other than cancer tend to experience less frequent or severe pain and a different array of symptoms. As demonstrated in 3 separate 2010 studies by Knapp, McCarthy, Jalmesell, and their colleagues, inadequate treatment of suffering in the care of children with life span-limiting conditions has significant effect on caregivers and can have lasting effects on bereavement.

This section provides a basic orientation to symptom assessment and management. Detailed description of intensive assessment methods and advanced management of the range of symptoms experienced by children with life span-limiting conditions is beyond the scope of this chapter. Readers are referred to excellent contemporary reviews by Kang and colleagues, Schwantes and O'Brien, Levine and colleagues, and Johnson and colleagues.

## Recognition and Effective Treatment of Pain

Physicians should follow an approach to analgesic use, introduced about 20 years ago, that is organized by "the ladder," by the clock, by the child, and by mouth (or by the least intrusive route) (Box 67-10). Since 2012, the WHO has promoted a 2-step approach to use of analgesics in children with medical illness who experience persistent or recurrent pain, in which acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID), such as ibuprofen, is used for mild pain, and an opioid is added for moderate to severe pain. Analgesics should be ordered on a standing basis (*by the clock*), according to the chosen analgesic and route of administration, rather than on an as-needed basis. Additional doses are available for breakthrough pain. When analgesics are provided only if the patient requests them, pain escalates between doses, the cumulative amount of analgesic administered is higher, and the potential for adverse effects is increased compared with when they are provided by the clock. The widespread undertreatment of pain, when ordered only on an as-needed basis, has led Friedrichsdorf to reinterpret the abbreviation "prn" to mean "patient receives nothing."

Unwarranted fears of addiction and confusion about the nature of tolerance and dependence inhibit some pediatricians from ordering opioid analgesics optimally for children and make some families reluctant to agree to their use. Tolerance to the analgesic

### BOX 67-10 Principles of Pain Management in Children

#### 1. By the ladder

Step	Pain Severity	Treatment
1	Mild	Oral acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs)
2	Moderate to Severe	Opioid analgesics; continue acetaminophen or NSAIDs

#### 2. By the clock

Analgesic treatment around the clock, rather than on a purely as-needed basis, results in

- Less frequent breakthrough pain
- Improved pain relief overall
- Fewer peaks and troughs of analgesic levels
- Less sedation

#### 3. By the child

Maximal suggested doses for acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are based on the child's weight. In contrast, most opioid analgesics have no maximal dose. The appropriate dose of an opioid is that which relieves pain without unacceptable adverse effects.

#### 4. By mouth (or by the least intrusive route)

Analgesic medication should be given by mouth, whenever possible, or by the least intrusive route, for mild to moderate pain. The parenteral route offers no advantages over the oral route other than more rapid onset of action.

Adapted from World Health Organization. *WHO Guidelines on the Pharmaceutical Treatment of Persistent Pain in Children with Medical Illness*. Geneva, Switzerland: World Health Organization; 2012. Available at: [apps.who.int/iris/bitstream/10665/44540/1/9789241548120\\_Guidelines.pdf](https://apps.who.int/iris/bitstream/10665/44540/1/9789241548120_Guidelines.pdf). Accessed January 5, 2016.

effects of opioids will develop after as little as 1 week, but usually after 2 or 3 weeks, of continuous use. Symptoms of dependence may appear if the drug is abruptly withdrawn after as little as 1 to 2 weeks. The complex psychosocial dysfunction and self-destructive pursuits that characterize addiction do not appear more frequently in children with life-limiting illnesses than in others.

Tolerance develops not only to the analgesic effects of opioids, but also to some of their adverse effects, such as sedation and pruritus. Unfortunately, constipation rarely lessens and should be managed proactively with laxatives, softeners, or both. If doses of opioids are increased and unacceptable adverse effects persist, then an alternative opioid agent can be substituted (a process called *opioid rotation*).

Appropriate pain control begins with proper assessment. Several validated scales for the appraisal of pain are readily available (eg, Face Legs, Activity, Cry, Consolability [FLACC]), including instruments adapted for use with children who cannot communicate easily. These scales must be used consistently and correctly. Observation of behavior is necessary for preverbal or nonverbal children, together with the use of validated

scales such as FACES and others listed in the review by Schwantes and colleagues. Self-report scales may be used for verbal children 3 years and older that use colors, poker chips, or cartoon faces to help children indicate the severity of their pain. Scales incorporating numerical ratings or visual analogs may be used in children older than 7 years who understand order.

The advice of pediatric pain specialists, more widely available in recent years, should be sought when analgesic regimens pose challenges. For children who quickly develop tolerance to the analgesic effects of opioids, who experience neuropathic pain, or who experience pain that might be amenable to regional epidural or nerve block, a pediatric pain expert should be a part of the care team.

### Recognition and Management of Other Symptoms

Fatigue is a prevalent and bothersome symptom near the end of life. It can be lessened by planned naps, limited interruptions during hospitalization, and efforts on the child's part to conserve energy. When excessive sedation is a persistent complication of opioid analgesics required for pain control, drug rotation or the addition of a stimulant such as caffeine or methylphenidate can be considered.

Anorexia is a subjective experience expected toward the end of life. By its nature, anorexia is unassociated with hunger. Traditional assessments of nutrition and hydration in these instances need not lead to medically provided interventions, such as intravenous fluids or nasogastric feeding. Forced hydration may lead to edema, dyspnea, and skin breakdown. Mouth care with moistening swabs, ice chips, and gentle hygiene is sufficient for many children with advanced disease.

Dyspnea can occur as the result of several processes related to the child's underlying condition, complications of treatment, and unrelated comorbidities. In addition to treating the underlying causes of the dyspnea, an approach focused on symptom assessment and palliation can lead to even greater relief. Opioid doses effective at relieving shortness of breath are smaller than those used for analgesia. Opioids are recommended for consideration in children with dyspnea on the basis of neuromuscular disease, whether or not the child is supported by mechanical ventilation. Simple environmental measures can be helpful, such as introducing fresh air and using fans to circulate air.

As is the case with dyspnea, pruritus may arise from the effects of the underlying disease, its treatment, and unrelated comorbidities. Environmental alterations, soothing baths and compresses, oral antihistamines, and topical corticosteroids and moisturizers, chosen as appropriate, can improve quality of life. In the setting of cholestasis, medications that bind bile salts are helpful.

The most successful management of constipation is anticipatory and often multimodal. It includes the use of softeners and laxatives, incorporation of high-fiber foods, and encouragement of physical activity as much as possible.

Nausea and vomiting can be lessened with antiemetic medication, the choice of which is guided by the

cause, and by dietary and environmental modifications. Some cognitive-behavioral methods and complementary and integrative treatments may be beneficial. Seizures are distressing to observe and may or may not warrant treatment, depending on frequency, intensity, and desire on the caregivers' part to minimize sedation.

Anxiety is common in children receiving treatment for serious illness and, in the care of children at the end of life, can complicate subsequent bereavement among caregivers, as reported by Jalsmell and colleagues. Interventions and support aimed at the cause are central. Delirium may be caused by metabolic abnormalities, infections, or adverse effects of drugs. Depressive symptoms are nearly universal among children with advanced illness and may be worsened by the adverse effects of disease treatment.

Increased attention is being paid to signs of autonomic instability, also called *dysautonomia*, which for years was recognized in survivors of traumatic brain injury and now is appreciated in many in children with severe neurologic impairment from a variety of causes. The signs can include irritability, crying, temperature instability, tachycardia, hypertension, tachypnea, sweating, and feeding intolerance. Because of the resemblance of these signs to manifestations of serious bacterial infection, children with autonomic instability undergo frequent evaluation and interventions aimed at diagnosis and treatment of infection, with the attendant pain and suffering associated with these interventions. Treatments aimed at moderating the instability, using gabapentin, clonidine, and other agents, can be immensely beneficial, but sedating as well.

Although much of the suffering experienced by children with life span-limiting conditions can be addressed with medication, the addition of numerous medications brings with it the risk for compound adverse effects resulting from polypharmacy. Sedative and anticholinergic side effects predominate.

## CONCLUSIONS

Improvements in palliative and end-of-life care for children have taken hold in the United States, decades after improved survival and disease-combating therapeutic successes. New palliative care pediatricians and teams are providing consultative care, guided by emerging knowledge about the epidemiology of life span-limiting conditions in childhood, children's and families needs and interventions that help, together with legislation requiring access to treatments formerly restricted for hospice enrollees. As pediatricians recognize children's need for palliative care and learn from the emerging data, they will be better able to provide basic palliative care to greater numbers of patients and families by addressing their emotional and spiritual needs, assessing and managing common symptoms and forms of suffering, facilitating advance care planning, participating in bereavement care, and recognizing indications for referral to specialists in pediatric palliative and hospice care.

Individuals involved in providing care to seriously ill children require support in processing their own experiences of loss. For some people, the rewards of working with devoted members of other disciplines and of the extreme closeness that can develop with

children and their families make providing this care the best work they can imagine. With attention to the information and guidance reviewed in this chapter, pediatricians can vastly improve care and caring for some of the sickest children and their families.

### Chapter 68

## CHILDREN EXPOSED TO ADVERSE CHILDHOOD EXPERIENCES

Andrew Garner, MD, PhD

Childhood adversity plays a prominent role in influencing a child's development and eventual life course. A wide array of adverse experiences in childhood have been associated with poor developmental outcomes as diverse as depression, substance abuse, teenage pregnancy, incarceration, emphysema, obesity, type II diabetes, and cardiovascular disease. Only recently, however, have advances in the neurosciences, epigenetics, and the physiology of stress begun to reveal the biologic mechanisms that might underlie these well-established associations. This chapter briefly reviews the epidemiologic associations between childhood adversity and unhealthy life course trajectories, and then defines toxic stress and discusses its effect on brain development. It also discusses ways in which pediatricians might intervene to minimize the potentially lifelong effects of childhood adversity.

### CHILDHOOD ADVERSITY AND LIFE COURSE TRAJECTORIES

Adversity can take many forms and can be either catastrophic/traumatic (eg, being abused or witnessing violence) or almost routine (eg, experiencing poverty or parental separation). Defining and measuring what makes an event “adverse” for a particular individual can be problematic. Is adversity dependent upon characteristics unique to the child (eg, the child's previous experiences, temperament, developmental state, or unusual physical or personal traits), the family situation (eg, childhood experiences of the parents, parental mental illness, or intimate partner violence), or broader societal issues (eg, poverty, unemployment, poor housing, neighborhood violence, or limited access to medical or mental health care)? Or, more likely, is adversity caused by complex interactions between all 3 ecologic levels? The perception of adversity or a threat can be quite variable, in that some children might have horrific experiences (witnessing interpersonal violence, for example) yet do very well, whereas other children might have long-lasting physiologic and behavioral changes resulting from relatively minor trauma (like seeing a barking and growling dog, or falling off a bike).

Despite this ambiguity about what constitutes adversity, numerous epidemiologic studies have demonstrated clear associations between various forms of

childhood adversity and multiple markers of poor physical and mental health as an adult. The Adverse Childhood Experiences (ACE) Study looked at more than 17,000 middle-class, middle-aged Americans (average age in the 50s) and found dose-dependent associations between the number of ACEs (see Table 68-1) and a wide array of outcomes, including markers for social functioning, sexual health, and mental health; risk factors for common diseases; and prevalent diseases (Box 68-1). The retrospective ACE Study and several smaller, prospective studies indicate that adverse experiences in childhood influence behavior, learning, mental wellness, physical health, and economic productivity decades later.

Because these epidemiologic studies are descriptive, no causal mechanisms can be asserted. However, interventional studies like the Perry Preschool Project and the Abecedarian Project have demonstrated that alterations in a child's developmental milieu have profound and enduring effects on behavior and health decades later, suggesting that early childhood experiences do alter life course trajectories in a meaningful way. Although econometric analyses of these early childhood interventions suggest a high return on investment, the salient features of these programs (child centered versus family or community centered) and the mechanisms underlying their success (promoting cognitive versus noncognitive skills) remain a topic of much debate.

### MEASURING ADVERSITY: THE PHYSIOLOGIC STRESS RESPONSE

Among the problems with quantifying childhood adversity are its subjective nature and the variability of individual responses. This suggests that the metric of adversity cannot be the precipitants of stress (or the adverse experiences themselves), but rather the individual's physiologic response to those precipitants. The physiologic mediators of stress (cortisol, adrenaline, etc) are quantifiable and can be measured both acutely (as stress reactivity—the magnitude of an acute stress response) or chronically (as elevated basal levels). Boyce and colleagues have looked at stress reactivity in children and have shown a high degree of variability. Traditionally, genetic predispositions were thought to play a major role in determining stress reactivity, but more recent data suggest that previous experiences also play an important role. Stress reactivity, much like brain development itself, results from a complex, dynamic interaction between genes (nature) and the environment (nurture) over time. Neural pathways activated in response to frequent environmental stimuli are strengthened by use. Frequent, strong, or prolonged stress responses early in life are thus able to “set” a relatively lower threshold for future stress responses and to promote a high degree of

Data from [www.cdc.gov/ace/prevalence](http://www.cdc.gov/ace/prevalence).

The Adverse Childhood Experiences (ACEs) Study asked more than 17,000 middle-class adults to recall if they had experienced any of these 10 ACEs prior to the age of 18 years. The prevalence of each ACE is given for both women and men. To determine an individual's ACE score, 1 point was given for each type of ACE recalled (for a maximum score of 10). Only 36% of the participants had an ACE score of 0, and 1 in 8 had an ACE score of 4 or more.

### **BOX 68-1** Adverse Childhood Experiences Are Associated With Numerous Measures of Poor Health

#### **A. SOCIAL FUNCTIONING**

1. High perceived stress
2. Relationship problems
3. Married to an alcoholic
4. Difficulty with job

#### **B. MENTAL HEALTH**

1. Anxiety
2. Depression
3. Poor anger control
4. Panic reactions
5. Sleep disturbances
6. Memory disturbances
7. Hallucinations

#### **C. SEXUAL HEALTH**

1. Young age of first intercourse
2. Unintended pregnancy
3. Teen pregnancy
4. Teen paternity

5. Fetal death

6. Sexual dissatisfaction

#### **D. RISK FACTORS FOR COMMON DISEASES**

1. Obesity
2. Promiscuity
3. Alcoholism
4. Smoking
5. Illicit drugs
6. Intravenous drugs
7. High perceived risk of human immunodeficiency virus (HIV)
8. Multiple somatic symptoms

#### **E. PREVALENT DISEASES**

1. Ischemic heart disease
2. Chronic lung disease
3. Liver disease
4. Cancer
5. Skeletal fractures
6. Sexual transmitted infections

All of these adolescent and adult outcomes are associated with Adverse Childhood Experiences (ACE) scores in a dose-dependent and statistically significant manner. From Garner AS. Home visiting and the biology of toxic stress: opportunities to address early childhood adversity. *Pediatrics*. 2013;132[Suppl 2]:S65-S73.

stress reactivity. Thus, although stress reactivity may be, to an extent, genetically programmed, it is nonetheless shaped by early individual experiences as well. This individual variability in stress reactivity might explain, at least in part, the wide range of long-term responses to adversity. In sum, it may not be the adverse entity itself that matters as much as the nature of the physiologic stress response that it invokes.

### **ADVERSITY AND STRESS ARE NOT ALWAYS NEGATIVE**

High stress reactivity, however, is not always a negative trait or one that invariably leads to maladaptive behavioral responses. In the context of low adversity, children with a high reactivity to stress (the so-called “orchids”) are actually more social and academically

successful than their peers with a low reactivity to stress (the so-called “dandelions”). However, in the context of high adversity, children with high reactivity to stress fare worse than their peers with low reactivity to stress. Hence, the consequences of high stress reactivity are contextual, with high reactivity promoting adaptive responses in the context of low adversity, but maladaptive responses in the context of high adversity. The relationship between adversity and stress is, therefore, complex. Adversity can promote stress reactivity, but stress reactivity can be beneficial in the context of low adversity.

In an attempt to refine this complex relationship between adversity and stress, the National Scientific Council on the Developing Child has proposed a taxonomy of stress based on the physiologic response to the event (Figure 68-1). Physiologic stress can be positive, tolerable, or toxic. Positive stress is infrequent, mild, or brief and is characterized by strong social-emotional (SE) supports. These strong SE supports—engaged, nurturing and invested caregivers—allow the child’s physiology to return to baseline, and they minimize the child’s exposure to the physiologic mediators of stress (like cortisol and adrenaline). Examples of adverse experiences that could trigger a positive stress response (and the SE supports needed to buffer that stress) include a toddler’s stumble or fall (under the reassuring eyes of a caregiver), a child’s anxiety over beginning kindergarten or child care (and an invested parent’s firm but sympathetic response), or the adolescent’s fear of failure on a long-term school project (that is overcome by a parent’s assistance in organizing time). SE supports effectively buffer the potentially “toxic” consequences of prolonged exposure to the physiologic mediators of stress (see the following section on Brain Development and Toxic Stress). More importantly, strong SE supports model effective social interactions and promote emotional regulation in the face of adversity, thereby building resilience. It is important to note that positive stress is not the absence of physiologic stress; rather, it reflects an ability to adapt to that stress in a healthy manner.

When compared to positive stress, tolerable stress is more frequent, intense, or sustained. Precipitants of tolerable stress might include the death of a loved one, a natural disaster, or a bully on the bus. Although these experiences have the potential to trigger physiologic responses that are stronger or more sustained, caregivers who are engaged, nurturing, and invested usually allow the child’s physiologic stress response to return to baseline. When compared to toxic stress, tolerable stress is distinguished by the presence of sufficient SE supports.

Conversely, toxic stress results from the frequent, strong, or prolonged activation of the body’s stress-response system in the absence of sufficient SE supports. Physiologic stress becomes toxic when it overwhelms the available SE supports and the child’s physiologic stress response is unable to return to baseline. The 10 childhood adversities studied in the ACE Study (see Table 68-1) are examples of potential precipitants of toxic stress. When a child’s SE supports are not engaged (eg, a caregiver who is impaired by

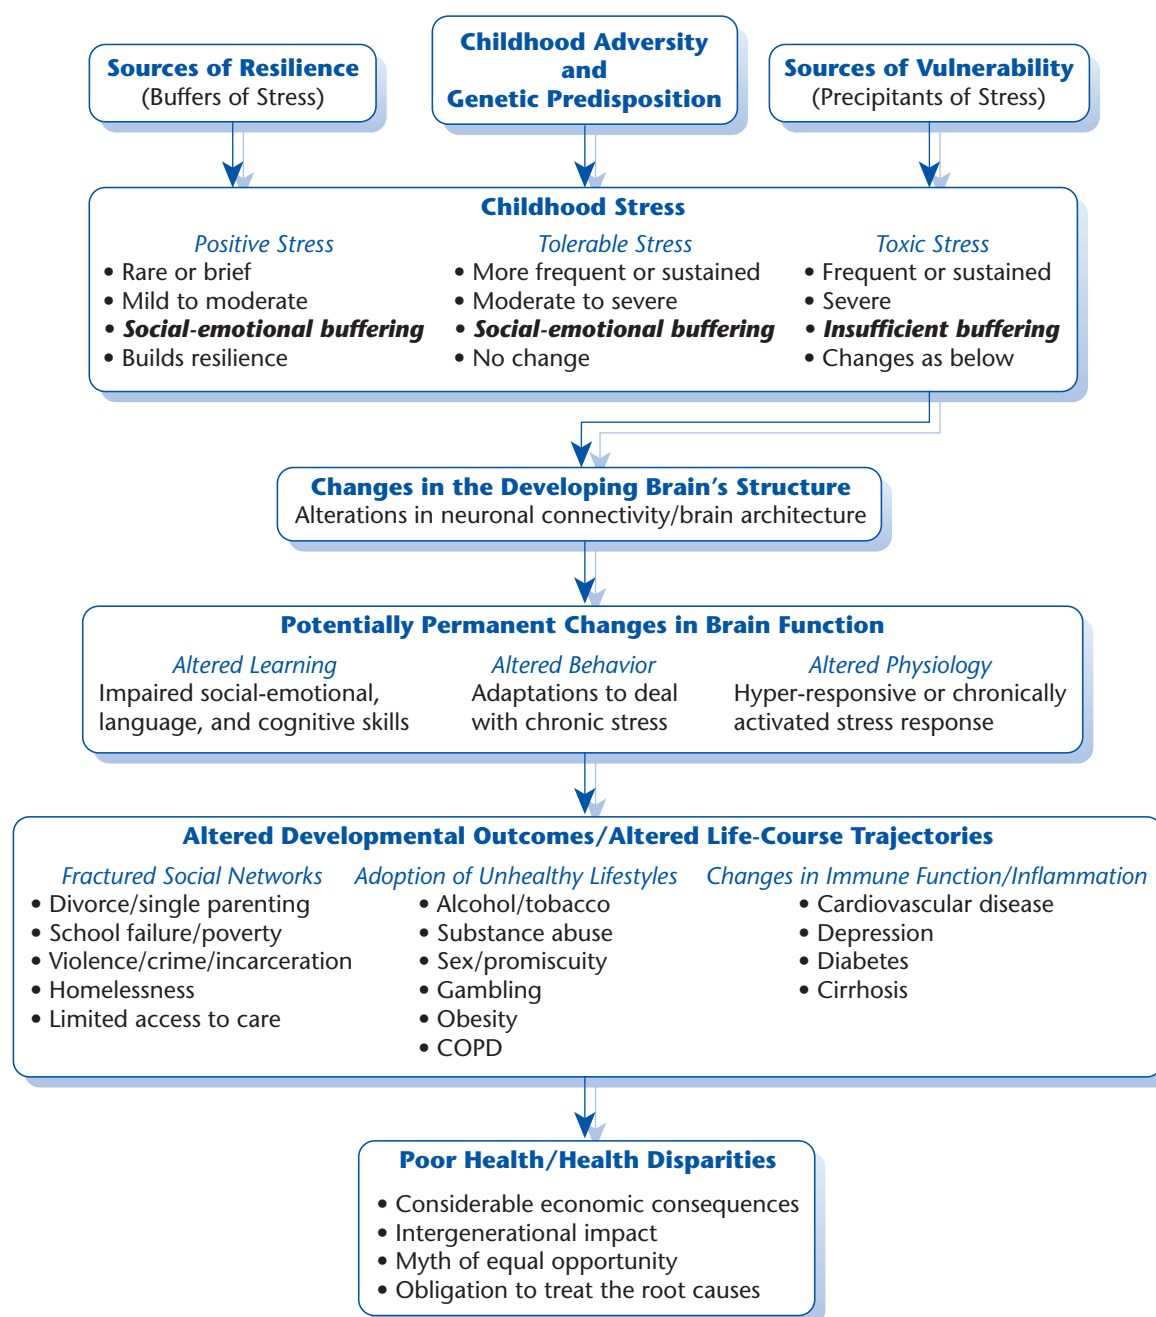

mental health or substance abuse issues) or nurturing (eg, a caregiver’s use of corporal punishment or verbal abuse), the child’s physiologic stress response is sustained, and biologic adaptations and disruptions begin to occur. Disengaged, non-nurturing caregivers may actually become sources of vulnerability, whereas engaged, nurturing caregivers are important sources of resilience. In sum, the relationship between adversity and stress is both complicated and dynamic. The type of stress response precipitated by adversity is influenced by the nature of the adversity, the individual’s stress reactivity, and the level of SE supports. (Are caregivers engaged and nurturing and building resilience, or are they disengaged, non-nurturing and generating additional vulnerabilities?)

## BRAIN DEVELOPMENT AND TOXIC STRESS

The process of brain development is driven by a dynamic interaction between the genome (nature) and the environment (nurture). Epigenetic mechanisms such as DNA methylation and histone acetylation are able to transduce experiences with the environment into long-lasting, even intergenerational changes in gene expression. Thus, while the inherited genetic program is thought to provide a general blueprint for brain architecture, the environment is able to influence which genes are expressed, when they are expressed during the course of development, and where they are expressed within the developing brain. Environmental experiences and the neuronal activity that they generate literally sculpt brain architecture and neuronal connectivity.

Understanding the effect of adverse experiences on the developing brain requires a brief review of where the physiologic mediators of toxic stress are acting in the brain. Glucocorticoid receptors are numerous in 3 prominent brain structures: the amygdala, the hippocampus, and the prefrontal cortex. The amygdala is part of the limbic system, is activated during stress, and is thought to play an important role in generating impulsive or aggressive behaviors. The fact that the amygdala is enlarged and more reactive in patients with post-traumatic stress disorder (PTSD) reinforces the notion that the neuronal pathways underlying the stress response (like those in the amygdala) are built up, reinforced, and strengthened by adverse experiences, leading to a hyperresponsive or chronically active stress response.

Another example of how stress might alter brain architecture is seen in the hippocampus. Although neuronal proliferation was once thought to occur only prenatally, new neurons are continuously being generated in the adult hippocampus, and these new neurons play an important role in learning and in the formation of new memories. In animal studies, chronic stress decreases this neuronal proliferation and results in impaired learning. Recent magnetic resonance imaging (MRI) data suggest that decreased hippocampal neurogenesis may well play a role in patients with PTSD, as they have selective volume losses in specific hippocampal areas known to be important for learning. While acute deficits in learning and memory might

**Figure 68-1** Toxic stress in childhood links adversity with poor health and health disparities. Adverse childhood experiences and genetic predispositions regarding stress reactivity interact to determine the type of childhood stress. Sources of resilience (strong social-emotional supports, previous adaptive experiences where adversity was successfully overcome, and the 7 Cs of resilience—Competence, Confidence, Connectedness, Character, Contribution, Coping, and Control) buffer this stress, whereas sources of vulnerability (poor SE supports, previous maladaptive experiences where adversity was not dealt with in a healthy manner, and harsh or abusive parenting) precipitate even more stress. Positive stress is rare or brief, mild to moderate in intensity, and builds resilience due to appropriate levels of SE buffering by invested, caring adults. Tolerable stress is more frequent or sustained, moderate to severe in intensity, and has the potential to alter life courses, but does not because of adequate levels of SE buffering. Toxic stress is often frequent, sustained, and severe in intensity, but is distinguished by the lack of sufficient levels of SE buffering. As a consequence, the physiologic mediators of stress (such as cortisol and adrenaline) become “toxic” to the developing brain, resulting in changes in brain architecture and functioning. These changes in brain structure and function are in turn associated with many of the adolescent and adult outcomes seen in the ACE study (see Box 68-1). Taken together, these altered developmental outcomes and maladaptive life course trajectories contribute to poor adult health and the intergenerational propagation of health disparities. (Adapted from Garner AS. Home visiting and the biology of toxic stress: opportunities to address early childhood adversity. *Pediatrics*. 2013;132[Suppl 2]:S65.)

be an evolutionarily advantageous, protective mechanism that allows individuals to “get over” very traumatic experiences, chronic or ongoing impairments in learning might also delay the development of critical social, emotional, language, and cognitive skills.

The prefrontal cortex is also altered by stress. The prefrontal cortex is thought to play an important role in executive function, including the regulation of behavior by suppressing impulses and emotions arising from the amygdala and other parts of the limbic system. In animal studies, exposure to chronic stress or glucocorticoids alters the synaptic connectivity within the prefrontal cortex, and this may limit the ability of the prefrontal cortex to suppress the impulsivity and aggression of the limbic system and to execute adaptive responses (rather than maladaptive responses) to future stress. Toxic stress-induced changes in brain structure explain, at least in part, the well-described effect of adversity on a variety of brain functions, including dysregulated physiologic responses (a hyperresponsive or chronically active stress response), poor learning (impaired memory), and maladaptive behaviors (difficulty in adopting adaptive responses to adversity).

### **TOXIC STRESS, DEVELOPMENTAL OUTCOMES AND LIFE COURSE TRAJECTORIES**

The toxic stress-induced changes in brain structure and function discussed earlier mediate, at least in part, the well-described relationship between adversity and altered life trajectories. A hyperresponsive or chronically activated stress response is likely to contribute to the dysregulated immune function and inflammation that are seen in those chronic diseases often associated with childhood adversity, like chronic obstructive pulmonary disease (COPD), cirrhosis, type II diabetes, depression, and cardiovascular disease. Toxic stress-induced impairments in critical SE skills and executive functions are likely to contribute to the fractured social networks associated with adults who have experienced childhood adversity. Examples include school failure, divorce, homelessness, poverty, violence, and limited access to health care. Finally, the adoption of maladaptive behaviors to deal or cope with chronic stress explains, at least in part, the association between childhood adversity and unhealthy lifestyle choices, such as alcohol, tobacco, and substance abuse; promiscuity; gambling; and obesity. Taken together, these 3 general classes of altered developmental outcomes or altered life trajectories (changes in immune function, fractured social networks, and unhealthy lifestyles) encompass many of the morbidities associated epidemiologically with childhood adversity.

### **IMPLICATIONS OF CHILDHOOD ADVERSITY AND TOXIC STRESS**

Childhood adversity and toxic stress are fundamental concerns for the medical community because unhealthy lifestyles, changes in immune function, and

fractured social networks are important markers of higher mortality, morbidity, and medical expenditures. Up to 40% of premature deaths are caused by behavioral patterns. The unhealthy lifestyles associated with childhood adversity are, at least in part, maladaptive coping responses to toxic stress. Another 25% to 30% of premature deaths are thought to be attributable to either social circumstances or shortfalls in medical care. Many of the consequences of fractured social networks associated with childhood adversity are known to contribute to these health care disparities. Toxic stress is also known to alter immune function and increase inflammatory markers, changes that are associated with morbidities as diverse as cardiovascular disease, viral hepatitis, liver cancer, asthma, COPD, autoimmune diseases, and depression. Childhood adversity and toxic stress are inherently medical concerns because they contribute significantly to poor health across the lifespan by encouraging the adoption of unhealthy lifestyles, widening social inequities and health disparities, and increased incidence of stress-associated, inflammatory diseases. Physicians in general and pediatricians in particular have an ethical obligation to address childhood adversity and toxic stress because they are important childhood antecedents, perhaps even determinants, of adult disease.

The consequences of toxic stress are enormous medically, socially, and economically. Advances in epigenetics demonstrate that early adverse experiences can alter gene expression patterns not only in the current generation, but in subsequent generations as well. Moreover, the fractured social networks and social inequities that often result from childhood adversity are prominent sources of toxic stress vulnerability for the next generation. These 2 facts, the epigenetic imprinting of the genome and the intergenerational cycle of social inequities, challenge assertions of “equal opportunity” and underscore the urgent need to address childhood toxic stress as a public health crisis.

### **CHILDHOOD ADVERSITY, TOXIC STRESS, AND PEDIATRIC CARE**

Pediatricians cannot address childhood adversity alone. Many of the systems that generate adversity for children (or serve as sources of vulnerability, such as family structure, income, housing, violence, etc) lie outside the walls of the pediatric clinic. Productive collaborations between pediatricians, family advocates, educators, judges, business leaders, and other stakeholders are needed to drive fundamental shifts in public policy and to promote more nurturing environments for children to live, grow, and learn.

Childhood toxic stress is a public health crisis, and addressing it will require a public health approach that includes treatment, targeted interventions for those at risk, and universal preventive measures. For children who have already experienced significant adversity, or have had previously supportive connections to family and community interrupted or severed by foster care or adoption, pediatricians play several critical roles. These include the recognition of potential signs of toxic

stress at various developmental stages, comfort in discussing possible precipitants of toxic stress with families, and familiarity with the available community resources that support the needs of families with children.

In addition to treatment, a public health approach to toxic stress would also embrace targeted interventions for those at risk. Routinely screening families for risk factors such as the parent's experiences as a child, substance abuse, mental illness, intimate partner violence, or food insecurity could identify children at risk for toxic stress. When linked to interventions, as in the Safe Environment for Every Kid model, these targeted screens are able to decrease important measures of childhood adversity like harsh parenting, maltreatment, and referrals to child protective services.

A public health approach to toxic stress must also include universal primary preventive measures. From a practical standpoint, however, eliminating all childhood adversity is both unfeasible and unadvisable. Some degree of adversity, once overcome, builds resilience, and some degree of stress, if not toxic, motivates behavioral change and learning (adaptation). The issue facing pediatricians and all other professionals caring for children is how to turn toxic stress into tolerable stress, and how to turn tolerable stress into positive stress. Recall that the 3 different types of stress are not defined by the stressors or adverse experiences themselves, but by the frequency, duration, and intensity of the physiologic stress response to those stressors. As seen in Figure 68-1, a very important determinant of the physiologic stress response is the degree of SE support or buffering.

At the practice level, then, pediatricians must assist parents and caregivers in providing developmentally appropriate forms of SE support. For example, beginning as early as the 2-month visit (see Connected Kids and Bright Futures in the Tools for Practice section at the end of this chapter), anticipatory guidance could address the appropriate response to the developing social smile, particularly for parents who might be depressed or overwhelmed. By nurturing the serve-and-return or transactional nature of the social smile, parents are strengthening attachment, promoting rudimentary social skills, and setting the foundation for language. As infants begin to coo and make happy vocalizations, parents need to reinforce those efforts (by cooing and smiling back) as effective alternatives to crying for attention. Attentive, calm, reassuring, and nurturing responses to infant distress model and promote emotional regulation.

In the second year of life, parents need to acknowledge and encourage the toddler's attempts to be competent and independent, while at the same time acknowledging that some important and consistent limits need to be maintained for safety. Continued vigilance for and reinforcement of emerging verbal and nonverbal modes of communication will stop or shorten many tantrums. As children reach their third and fourth years, tantrums and conflicts are opportunities to address the behavior ("no biting") and, more importantly, to demystify the strong emotions that are often underlying the behavior ("I understand that you are angry, but biting doesn't help anger. Next time you are angry, let's try to use our words, or maybe we

can take turns, or maybe we can find something else to do"). This sort of emotion coaching models problem solving, teaches new coping strategies, buffers future stress, and builds resilience, even in the face of severe adversities. These positive parenting techniques (building on strengths while teaching and nurturing emerging new skills) build resilience, in contrast with harsh or physical means of discipline that, while sometimes effective in the short term, only promote aggression and serve as sources of vulnerability in the future.

For young children, SE supports are primarily external. Parents and invested caregivers provide a predictable, nurturing environment to minimize the child's exposure to the physiologic mediators of stress; model healthy, adaptive responses to stress; and reinforce the child's rudimentary or emerging SE skills (engaging others, language skills, self-soothing, etc). For parents and caregivers who are unable to provide these supports, medical homes must be familiar with evidence-based parenting programs (eg, Triple P), home visitation programs (eg, the Nurse Family Partnership), and quality early childhood education services (eg, Head Start).

In adolescence, however, the peer group may become a major source of SE support, in some cases eclipsing the support provided by family. This can leave some youths susceptible to peer pressure and to the temptation to act in a certain way to receive additional SE support. Youths who are experiencing toxic stress may be more likely to seek this additional SE support from their peer group, even if those peers are less than ideal SE role models.

The primary goal for older children, therefore, is to build internal SE supports prior to adolescence. Internal SE skills (like the 7 Cs of resilience—a child's internal sense of competence, confidence, connectedness, character, contribution, coping, and control) need to be the objectives of parents, pediatricians, teachers, and all other professionals who care for children. These critical SE skills will not insulate children from all adversity, but they may turn tolerable or even toxic stress responses into positive ones.

## SUMMARY

Framing childhood adversity in the context of the physiologic response begins to explain the strong associations between adverse experiences in childhood and a wide array of altered developmental outcomes and life course trajectories. This physiologic framework also suggests a generalizable, proactive approach to mitigating the potentially lifelong consequences of childhood adversity—minimize toxic stress by assisting families of young children and strengthening critical SE supports early in life.

### Chapter 69

## CARING FOR FAMILIES NEW TO THE UNITED STATES

Rashmi Shetgiri, MD, MSHS; Hema N. Magge, MD, MS;  
Paul L. Geltman, MD, MPH; Glenn Flores, MD

### INTRODUCTION

The United States is a nation of immigrants. Since 1820, an estimated 75,356,720 people have immigrated to the United States. Currently, almost 3 million foreign-born children live in the United States, accounting for 1 in 27 American children. Twenty percent of children under the age of 6 are the children of immigrants, and are the

fastest growing population of children in the United States. This chapter provides a comprehensive approach to providing high-quality health care to immigrant children. Recent detailed reviews of immigrant health care have focused on screening tests and checklists. In addition to reviewing important medical and health-promotion topics for immigrant children, this chapter addresses basic demographics, barriers to health care, and linguistic and cultural issues for immigrant and refugee children in the United States.

## DEMOGRAPHICS OF IMMIGRANTS AND REFUGEES

In 2009, 1,130,818 immigrants received legal resident status in the United States, of which 177,368 were refugees or asylees. The 5 largest countries of origin of immigrants to the United States are (in order) Mexico, China, the Philippines, India, and the Dominican Republic (Figure 69-1). Most US immigration is through sponsorship by relatives, with 47% being immediate family members of US citizens and 19% receiving family sponsorship (Figure 69-2).

Official immigration figures, however, do not account for the large numbers of undocumented immigrants living and working in the United States. Among the estimated 11.1 million undocumented immigrants in the United States, 10%, or 1.1 million, are children. The annual flow of undocumented immigrants into the United States declined from 2007 to 2009.

## ACCESS TO HEALTH CARE IN THE UNITED STATES

The pediatric primary care physician should consider financial issues and insurance coverage when providing care to immigrant families. With implementation of the federal Patient Protection and Affordable Care Act (PPACA), financial issues and insurance coverage should become less of a problem for documented immigrants. At present, they pose significant barriers to care for many families. For example, 52% of foreign-born noncitizen children are uninsured, compared with 15% of US-born children in citizen families. More than one-fourth (28%) of foreign-born noncitizen children have no usual source of care (other than the emergency department), compared with approximately 6% of US-born children in citizen families. Foreign-born noncitizen children also are less likely than US-born children to have visited a doctor, dentist, or mental-health specialist. Low-income noncitizen children are approximately 5 times as likely to be uninsured as similar children in citizen families, and only 20% of low-income noncitizen children participate in Medicaid or the Children's Health Insurance Program (CHIP), compared with approximately one-half of low-income citizen children (49% for citizen children in noncitizen families and 41% for citizen children in citizen families). The American Academy of Pediatrics advocates for "comprehensive, coordinated, and continuous health services provided within a medical home..." for immigrant children, and awareness of and sensitivity to financial and other barriers that "interfere with achieving optimal health status." An unfortunate start to a

**Figure 69-1** Top countries of origin of immigrants to the United States—2009.

**Figure 69-2** Distribution of legal classifications of immigration visa sponsorship for immigrants to the United States in 2009.

pediatrician's relationship with new patients who are uninsured immigrants would be to perform a large battery of screening laboratory tests and unintentionally cause financial burden to the family.

Studies of Latino children indicate a wide variety of other access barriers to care for immigrant children. For example, a study of a predominantly immigrant Latino population revealed that more than one-quarter of parents (26%) said that language problems were the single greatest barrier to getting health care for their child (specifically, 15% of parents said that the greatest obstacle was physicians and nurses who do not speak Spanish, and 11% cited lack of interpreters). A long wait at the physician's office was reported as the greatest barrier by 15%, 13% mentioned the lack of medical insurance, 7% cited difficulty paying for medical bills, and 6% identified transportation. Parents who participated in the study also identified several barriers to care that had caused them not to bring their child in for medical visits in the past; transportation problems

were reported most often (21%), followed by not being able to afford health care (18%), excessive waits to see the physician (17%), lack of health insurance (16%), inconvenient clinic hours (14%), difficulty making appointments (13%), and culture and language problems (11%).

Access to primary care and other medical services can be highly variable among immigrant communities. Racial/ethnic minorities and low-income children in the United States consistently have had significantly worse rates of having a usual source of care and other health care indicators. In addition, specific ethnic groups have varying levels of access to and use of health care even within their own communities. These differences, independent of income and educational levels, underscore the importance of cultural and linguistic barriers to healthcare access. Accordingly, outreach to ethnic communities and the provision of comprehensive language services to all those who need them are important steps in improving access to healthcare.

Other research on the largest racial/ethnic group among US immigrants, Latinos, suggests that health insurance coverage is a major determinant of access to and use of care. A large study of Latinos in Los Angeles found that a lack of employment-linked health insurance posed a significant barrier to care for children. Many Latino immigrant children live in 2-parent households, with parents (particularly non-citizens) working in entry-level jobs without benefits or the ability to afford health care insurance premiums. Similarly, children with working parents who were eligible for Medicaid were less likely than others to be continuously enrolled. Children in this category also had less access to care in all measures studied. Indeed, research documents that, after adjustment, parental noncitizenship, having 2 parents work, low family income, and older child age are associated with being an uninsured child, but Latino ethnicity is not. In states where undocumented immigrant children are eligible for at least limited health insurance coverage, *promotoras* and other community health workers can be highly effective means of insurance outreach and enrollment. For example, one randomized, controlled trial of an insurance intervention for Latino children that included many immigrant families documented that community healthworkers were substantially more effective than traditional Medicaid and CHIP outreach and enrollment in insuring children (at 96% vs 57%, respectively), and community health workers insured children significantly faster, more continuously, and with higher parent satisfaction with the process.

Federal welfare and immigration reform legislation in 1996 further restricted access to Medicaid for noncitizens to reduce expenditures and discourage immigrants from becoming public charges. Nonetheless, research has documented that in the 2 years before enactment of this legislation, immigrants had substantially lower *per capita* healthcare expenditures (55%) than their US-born counterparts. Among children, expenditures were 74% lower among immigrants, yet emergency-department expenditures were 3 times higher. The latter finding suggests that immigrant children are going without basic primary care services and are missing out on the benefits of

a medical home. A recent study of immigrant children's use of public health insurance since reform legislation shows that foreign-born children were 1.6 times more likely to be uninsured after 2001 than before 2001, and are 3 times more likely to be uninsured than to have public insurance. The PPACA of 2010 increases Medicaid coverage to 133% of federal poverty level and restricts access to the health-insurance exchange to US citizens and legal residents. It does not alter current restrictions on Medicaid and CHIP eligibility for legal permanent residents within the first 5 years of residency, or for undocumented immigrants. Although the ACA contains a provision for the development of guidelines to reduce health disparities through methods such as the use of language services and cultural competency training, the payment mechanism for these services will be incentive-based. The Act does not require insurance plans to reimburse for language services or translation of materials into languages other than English, and only 13 states and the District of Columbia currently provide third-party reimbursement for interpreter services.

Of note, there are nearly 4 million children born in the United States to undocumented immigrants who may encounter even further barriers to productive and healthy futures, despite their citizenship status. Recent research found that children of undocumented immigrants may have lower early cognitive and language skills than children of documented immigrants of similar socioeconomic backgrounds. Undocumented parents may share circumstances that adversely affect their children's outcomes such as avoidance of programs and authorities, social isolation, and poor work conditions. Fearing deportation, undocumented immigrants may be reluctant to access services such as early education programs and food subsidies that could be essential to improving child development. Poor work conditions, including lower rates of benefits and lower wages, may also lead to less access to child care subsidies and center-based care. These factors may contribute to ongoing parental stress and economic hardship, which may result in less of the parent-child interaction that is critical to early skill development in children.

Pediatricians and hospitals that care for children increasingly are facing the dilemma of rationing care to uninsured, undocumented immigrant children, particularly for expensive, life-saving pediatric care, including transplants, chemotherapy, and dialysis. For example, some hospitals have policies to provide neither dialysis nor kidney transplantation to undocumented, uninsured end-stage renal-failure patients. In such cases, it can be argued that the high costs associated with providing expensive lifesaving care to undocumented children can compromise existing or new clinical programs. On the other hand, denying acute and chronic care to undocumented immigrant children may result in higher overall expenditures related to preventable hospitalizations and more expensive therapies and have unintended public-health consequences, including significant long-term morbidity and a high risk of early mortality. One potential solution which has been suggested is to have hospitals and clinics establish a structured process with a panel

of pediatricians and hospital staff who would evaluate these considerations and make a recommendation on a case-by-case basis. This approach could result in formulating a medical individual expense plan for uninsured, undocumented children that could include providing financial aid, discounted treatment, payment plans, and philanthropic support and active fund-raising for lifesaving care.

## HEALTH PROMOTION

Primary care physicians working with families new to the United States must first establish relationships with the families that are linguistically and culturally effective (see details on cultural competency action steps later in this chapter). By showing interest in the families' background, culture, and community issues, the physician may also gain a reputation as a sympathetic and supportive healthcare provider whom other members of that ethnic community can trust. The following section describes in more detail the issues associated with this task. An important point to remember is that postponing medical screening is reasonable if it seems inappropriate based on cultural, linguistic, or economic reasons.

The process of health promotion and preventive medicine may be new to the family. This process is informed by knowledge of the family's home and social circumstances, with which the physician can assess the family's previous experience with the health care system as well as the level of need for environmental intervention, injury prevention, and mental-health services. In trying to understand the cultural expectations of immigrant patients and families and introducing concepts of health promotion and preventive medicine, the physician will embark on a journey of communication with new Americans. This journey may be relatively straightforward and brief with patients and families who share more Western beliefs, or it may involve multiple levels of complexity that will require a fair amount of time and effort. Efforts should be made to understand immigrant families' previous experiences with the health care system in their native countries; educate them about basic issues in the American health care system, such as assessing eligibility for and access to health insurance; and to provide practical tips, such as instructions on where to go for urgent care and when to go the emergency department.

## LANGUAGE BARRIERS TO CARE AND PROVIDING ADEQUATE LANGUAGE ACCESS

Approximately 57 million Americans speak a language other than English at home, and 24.6 million are limited in English proficiency (LEP), defined as a self-rated English-speaking ability of less than "very well." As of 2009, approximately 11 million (21%) US school-aged children (5 to 17 years old) spoke a language other than English at home, almost triple the number reported in 1979, and 2.6 million (5%) were LEP. Between 1980 and 2009, the number of people in the United States speaking a language other than English at home increased from 23 million to 57 million. The number of Americans who are LEP rose from 14 million in 1990 to 24.6 million in 2009.

This marked growth in the number of Americans who speak a language other than English at home or who are LEP can be attributed to the rapid increase in the foreign-born population in the United States, which grew from 9.6 million in 1970 to 38.5 million in 2009. Most Americans considered to be LEP (66%, or 16.2 million) speak Spanish; Asian and Pacific Island languages (led by Chinese) are the next most common among LEP Americans (comprising 17%, or 4.2 million), followed by other Indo-European languages (14%, or 3.4 million), and all other languages (3%, or 750,000).

Language barriers have many adverse consequences in health care, including impaired health status, a lower likelihood of having a usual source of medical care, lower rates of screening and other preventive services, nonadherence with medications, a greater likelihood of a diagnosis of more severe psychopathology and leaving the hospital against medical advice among psychiatric patients, a lower likelihood of being given a follow-up appointment after an emergency-department visit, an increased risk of intubation in asthmatic children, an increased risk of drug complications, higher resource utilization for diagnostic testing, lower patient satisfaction, impaired patient understanding of diagnoses, medications, and follow-up, fewer telephone calls to physicians' offices, fewer referrals to specialists, and an increased risk of medical errors and injuries. Latino parents consider the lack of interpreters and Spanish-speaking staff to be the greatest barriers to health care for their children, and 1 out of every 17 parents in one study reported not bringing his or her child in for needed medical care because of these language issues.

To assess the language needs of patients and caregivers accurately, determining whether a child's caregiver is LEP is essential. Determining English proficiency has been shown to be superior to the primary language spoken at home as a measure of the effect of language barriers on children's health and health care. The following questions, which come from the US Census, are an excellent means of quickly assessing English proficiency and language needs and should be asked routinely of the primary caregiver during the 1st visit:

1. Does this person speak a language other than English at home?
  - Yes
  - No [*Stop here; person is considered English proficient*]
2. What is this language?  
(*For example: Korean, Italian, Spanish, Vietnamese*)
3. How well does this person speak English?
  - Very well
  - Well
  - Not well
  - Not at all

[*Person is LEP if reply is anything other than "very well" and requires medical interpreter or bilingual provider.*]

Although millions of Americans are LEP, many patients who need medical interpreters are not provided with interpreters. Every LEP patient should have access to a trained medical interpreter or bilingual health care provider. Ample scientific evidence documents that optimal communication, patient satisfaction, and

outcomes, and minimal interpreter errors occur when LEP patients have access to trained professional interpreters or bilingual providers. In addition, federal guidance on Title VI of the Civil Rights Act of 1964 has established that denial or delay of medical care for patients who are LEP because of language barriers constitutes a form of discrimination and requires all recipients of federal funds, including Medicaid, CHIP, and Medicare, to provide adequate language assistance to those who need it. Key mechanisms for ensuring adequate language access for patients and families who are LEP are summarized in Box 69-1.

Detailed information on improving language access in health care is available in the Office of Minority Health's "A Patient-Centered Guide to Implementing Language Access Services in Healthcare Organizations."

## CULTURAL ISSUES

Cultural issues affect multiple aspects of pediatric care, including outcomes, quality, costs, satisfaction with care, and patient safety. Failing to appreciate the importance of culture in pediatrics can result in a variety of adverse consequences, including difficulties with informed consent; miscommunication; inadequate understanding of diagnoses and treatment plans by families; dissatisfaction with care; preventable morbidity and mortality; unnecessary child-abuse

evaluations; and disparities in prescriptions, analgesia, and diagnostic evaluations. On the other hand, providing culturally competent health care to children is associated with better health outcomes. For example, pediatric patients with asthma receiving care at practice sites with the highest cultural competence scores are significantly less likely to be underusing preventive asthma medications and have better parental ratings of the quality of care.

Because culture can profoundly affect the care of immigrant children, pediatricians should be familiar with the most important cultural issues that affect clinical care, including folk illnesses with symptoms that overlap with biomedical conditions, biomedical conditions that can result from harmful folk illness remedies or parental beliefs and practices, and cultural healing practices that can be confused with child abuse. Table 69-1 through Table 69-3 are organized by folk illnesses based on regional origin. Although this is not a comprehensive list of folk illnesses and there may be some overlap between regions, the tables can allow physicians to immediately locate cultural information relevant to their prevalent patient populations. These 3 tables can be helpful in obtaining accurate histories and improving patient satisfaction through the use of culturally acceptable alternative treatments (see Table 69-2), generating

### BOX 69-1 Key Mechanisms for Ensuring Adequate Language Access for Patients, Caregivers, and Families With Limited English Proficiency

- **Ensure that a trained medical interpreter or bilingual provider is available for each medical encounter.** Making language available throughout the encounter is especially important, including during registration, the history and physical, procedures, visits to the laboratory and radiology, and scheduling of follow-up appointments.
- **Use telephone or video interpreter services when in-person interpreters or bilingual providers are unavailable.**
- **Ensure adequate language access *door-to-door* (ie, at all points of interaction with the health care system).** This provision includes multilingual operators, telephone trees, or both (for scheduling appointments, leaving messages and getting phone advice), multilingual signage at all key wayfaring points (parking garages, clinic entrances, registration, paths to the emergency department, laboratory, radiology, and pharmacy), and multilingual registration clerks.
- **Routinely collect and record patient and family data on primary language spoken at home and limited English proficiency.** This provision permits efficiently meeting the language needs of the patient population and scheduling interpreters in advance for all future medical visits.
- **Use pharmacies that can print prescription labels, provide medication information packets, and communicate in non-English languages.** Failure to do so can result in medical errors and injuries. Printing clinic prescription pads with checkboxes such as ☐ *Spanish* or ☐ *Chinese* is particularly helpful and is a useful reminder.
- **Have patient information and anticipatory guidance pamphlets available in non-English languages common in the physician's practice.** Ideally, certified translators should be available to translate written documents for patients. Useful Web resources with materials already translated include the National Network of Libraries of Medicine Other Language Resources site ([nnlm.gov/outreach/consumer/multi.html](http://nnlm.gov/outreach/consumer/multi.html)), US Department of Health and Human Services' Español-Healthfinder ([www.healthfinder.gov/espanol/](http://www.healthfinder.gov/espanol/)), CDC en Español ([www.cdc.gov/spanish/](http://www.cdc.gov/spanish/)), and Selected Patient Information Resources in Asian Languages ([www.spiral.tufts.edu/](http://www.spiral.tufts.edu/)).
- **Translate consent forms into all relevant non-English languages for your patient population.**
- **Help patients and families who are LEP to learn English through referrals to free or low-cost English as 2nd-language courses.** This excellent resource ([www.literacydirectory.org](http://www.literacydirectory.org)) locates classes according to zip code.
- **Increase the number of bilingual health care providers and staff.** This provision can be achieved through enhanced efforts to recruit bilingual staff, continuing professional education, intensive language courses, and bonuses for demonstrating foreign language fluency.

**Table 69-1** Selected Folk Illnesses With Symptoms That Overlap With Biomedical Conditions Affecting the Health Care of Children

REGIONAL ORIGIN	FOLK ILLNESS	ETHNICITY OR NATIONALITY THAT MAY HAVE FOLK ILLNESS BELIEF		SYMPTOMS OF FOLK ILLNESS	BIOMEDICAL CONDITIONS THAT OVERLAP WITH FOLK ILLNESS
Latin America	<i>Empacho</i> (and <i>pega</i> )	Latino		Vomiting, stomach pain, headache, abdominal distention, loss of appetite, diarrhea, fever, crying	Gastroenteritis, viral infections, milk allergy, appendicitis, intussusception, anatomic obstruction, lead poisoning
	<i>Caida Mollera</i>	Latino		Diarrhea, excessive crying, fever, loss of appetite, irritability, fallen fontanelle	Gastroenteritis, dehydration, sepsis, meningitis
	<i>Susto</i>	Latino		Drowsiness, insomnia, irritability, exaggerated startle reflex, diarrhea, anorexia, fever, nightmares	Persistent symptoms after pesticide toxicity
	<i>Mal Ojo, Quebrante or Olhado</i>	Latino Brazilian		Inconsolable crying, fever, diarrhea, vomiting, pain, gassy stomach	Gastroenteritis, dehydration
	<i>Quebranto</i>	Costa Rican		Irritability, crying, leg-length discrepancy	Developmental dysplasia of the hip
Africa	<i>Doença de Criança</i>	Brazilian		Diarrhea, fallen fontanelle, convulsions, cyanosis, crying, vomiting (and 17 other less common symptoms)	Gastroenteritis, dehydration, malaria, bacterial meningitis, dengue, measles, pneumonia, methemoglobinemia, pesticide poisoning
	<i>Ventre Caído</i>	Brazilian		Vomiting, diarrhea, loss of appetite, fatigue, cough	Gastroenteritis, dehydration
	<i>Nyènkèhè biènkè</i>	Mali		Red urine	Schistosomiasis
	<i>Umsheko</i>	Swaziland		Wet, loose, nongreen stools accompanied by grumbling stomach, loss of appetite, vomiting	Gastroenteritis, dehydration
	<i>Kuhabula</i>	Swaziland		Sunken fontanelle, loss of strength, vomiting, crying, ribs <i>appear</i> to come together	Gastroenteritis, dehydration
Indian subcontinent	<i>Umphezulu</i>	Swaziland		Green or yellow diarrhea, unusual crying, loss of appetite, distended stomach or navel, grumbling stomach, sunken fontanelle, blood vessels visible on stomach or forehead	Gastroenteritis, dehydration
	<i>Mandama</i>	Singhalese (Sri Lanka)		Diarrhea, abdominal distention, lethargy, <i>lean</i> legs	Gastroenteritis, dehydration
	<i>Dud haga</i>	Rural Bangladesh		Watery stools, crying, abdominal pain	Gastroenteritis, dehydration
	<i>Ajirno</i>	Rural Bangladesh		Diarrhea, abdominal distention, gripping of the stomach	Gastroenteritis, dehydration
	<i>Amasha</i>	Rural Bangladesh		Mucoid and sometimes bloody diarrhea	Gastroenteritis, dehydration, dysentery
	<i>Daeria</i>	Rural Bangladesh		Frequent stools with rice-water appearance, sunken eyes, thirst, vomiting, reduced urine output, weakness	Cholera, gastroenteritis, dehydration

Table 69-1

Selected Folk Illnesses With Symptoms That Overlap With Biomedical Conditions Affecting the Health Care of Children—cont'd

REGIONAL ORIGIN	FOLK ILLNESS	ETHNICITY OR NATIONALITY THAT MAY HAVE FOLK ILLNESS BELIEF	SYMPTOMS OF FOLK ILLNESS	BIOMEDICAL CONDITIONS THAT OVERLAP WITH FOLK ILLNESS
Asia and Pacific Islands	<i>Phrooy</i>	Northern Pakistan	Green diarrhea, blisters on body, infections of the ear and eye	Gastroenteritis, dehydration
	<i>Sarishna</i>	Northern Pakistan	Green watery stools, burning yellow urine, weakness, eyes turned upward	Gastroenteritis, dehydration
	Loose motions	Northern Pakistan	White watery stools, fallen fontanelle	Gastroenteritis, dehydration
	<i>Sardawan</i>	Northern Pakistan	Frequent green watery stools, sunken eyes, weakness	Gastroenteritis, dehydration
	<i>Maleeh</i>	Northern Pakistan	Yellow or green watery stools	Gastroenteritis, dehydration
	<i>Saya</i> or <i>parchawan</i>	Northern Pakistan	Persistent green, white, or yellow diarrhea	Gastroenteritis, dehydration
	<i>Nazar</i> (evil eye)	Northern Pakistan	Green watery stools, fever, sunken eyes, dry lips, weak extremities	Gastroenteritis, dehydration
	<i>Kand-pota</i> (fallen fontanelle)	Northern Pakistan	Watery green stools, vomiting	Gastroenteritis, dehydration
	<i>Sardi</i> or <i>Padsa</i>	Marathas (India)	Cough, runny nose, congested chest, fever	Mild upper respiratory infection
	<i>Potat ala</i>	Marathas (India)	Labored respirations, stomach "going up and down," fever, phlegm, cough, congested chest	Moderate to severe respiratory infections, including pneumonia
	<i>Paltha dabba</i>	Marathas (India)	Tight or hard stomach (worse at night), cough, eyes closed, nostrils flare, fisted hands	Severe pneumonia
	<i>Phagya vat</i>	Marathas (India)	Tight or hard stomach, anorexia, constipation	Moderate to severe respiratory infections, including pneumonia, lead poisoning
	<i>Kitsune-tsuki</i> (fox possession)	Japanese	Delusions, disordered thinking, auditory hallucinations, paranoia	Psychosis, schizophrenia, mercury poisoning
	<i>Piang</i>	The Philippines	Cough, fever	Acute respiratory infection, including pneumonia
	<i>Naeng</i>	Korea	Vaginal discharge, back pain, cold hands and feet, abdominal pain, vaginal itching	Vaginal candidiasis, sexually transmitted diseases

**Table 69-2** Biomedical Conditions in the Health Care of Children That Can Result from Harmful Folk Illness Remedies or Parental Beliefs and Practices

REGIONAL ORIGIN	CONDITION	ASSOCIATED FOLK ILLNESS, PARENTAL BELIEF, OR SYMPTOM	ETHNICITY OR NATIONALITY THAT MAY HAVE FOLK ILLNESS OR PARENTAL BELIEF	HARMFUL TREATMENT ASSOCIATED WITH CONDITION	CULTURALLY ACCEPTABLE ALTERNATIVE FOLK TREATMENTS
Latin America	Lead poisoning	<i>Empacho</i>	Latinos	Powders containing lead oxides ( <i>azarcón, greta, albayalde</i> )	Abdominal massage with warm oil, mint tea
	Subdural hematoma	<i>Caida de mollera</i>	Latinos	Infant shaken while held upside down with head partially immersed in boiling water	Put soap foam on fontanelle
	Gonococcal conjunctivitis	Conjunctivitis	Latinos <sup>a</sup>	Adult urine as treatment for conjunctivitis in children	Gently push up on palate
	Disseminated <i>Salmonella arizonae</i> infections	Sinus and skin conditions, diarrhea, infections, itchy feet, AIDS, diabetes, connective tissue diseases, heart disease, cancer	Latinos	Capsules or powder containing dried ground rattlesnake, raw dried rattlesnake meat: <i>polvo de vibora, carne de vibora, vibora de cascabel</i>	Special diet: vegetable soup and fresh fruits, carrot juice, eliminate flour tortillas, bread, soda
	Hepatic veno-occlusive disease	Cough	Latinos		Variety of harmless, disease-specific herbal preparations
Africa	Wound infection or cellulitis around infant's umbilicus	<i>Umphezulu</i> (type of diarrhea)	Swaziland (Africa)	<i>Gordolobo yerba</i> , tea made from herb <i>Senecio longilobus</i> , which contains hepatotoxic pyrrolizidine alkaloids <i>Traditional vaccination (kugata)</i> : razor blade cuts made around infant's umbilicus rubbed with ashes	Herbal teas using small amounts of oregano, cinnamon, or chamomile (not sweetened with honey) Herbal teas
	Urinary retention, dysuria, urinary tract infections, incontinence, fever, menstrual difficulties, cysts, abscesses, fistulae, obstetric complications, vaginal pain, bleeding discharge	Reasons cited by cultures for practice: tradition, group identity or norms, chastity, marital reasons, hygiene	Widespread in 33 African nations, most commonly Somalia, Djibouti, Ethiopia, Eritrea, Sudan, Sierra Leone; certain Islamic peoples in Asia, Middle East	Female circumcision, genital mutilation, <i>Sunna</i> , infibulation, Pharaonic circumcision, traditional or ritual female genital surgery	Education regarding health risks; discuss culturally-acceptable alternatives with community or religious groups; advocacy against procedure by community, religious, women's and law organizations; use of least damaging procedure (such as small nick/incision of prepuce) in families insisting on practice

**Table 69-2** Biomedical Conditions in the Health Care of Children That Can Result from Harmful Folk Illness Remedies or Parental Beliefs and Practices—cont'd

REGIONAL ORIGIN	CONDITION	ASSOCIATED FOLK ILLNESS, PARENTAL BELIEF, OR SYMPTOM	ETHNICITY OR NATIONALITY THAT MAY HAVE FOLK ILLNESS OR PARENTAL BELIEF	HARMFUL TREATMENT ASSOCIATED WITH CONDITION	CULTURALLY ACCEPTABLE ALTERNATIVE FOLK TREATMENTS
Indian subcontinent <sup>b</sup>	Dehydration	<i>Dud haga</i>	Bangladesh	1. Breastfeeding discontinued because (a) breast milk considered <i>poisoned</i> by shadow, evil eye, black magic, new pregnancy, illness, diet, cold; (b) pseudoscientific laboratory <i>breast milk analysis</i> reveals pus, germs, mobile bacteria, or blood (Pakistan) 2. Reduce child's oral intake of liquid because liquid believed to worsen diarrhea or vomiting feared Give formula until breast milk no longer considered <i>poisonous</i>	Mother avoids eating green vegetables, fish, meat
		<i>Nazar</i>	Pakistan		Apply <i>chanted oil</i> (available from folk healers, Buddhist priests); Education
		<i>Eshwaha</i> , diarrhea in general	Sri Lanka		Rub ghee (clarified butter) on abdomen Education; ascertain whether multivitamin drops are acceptable replacement Replace with saline drops
	Burns in circular pattern on abdomen Lead poisoning (including death) Lipoid pneumonia, bronchiectasis	<i>Phugrya va</i> (respiratory illness) Maintenance of infant health Cleaning airway of newborn; treatment of respiratory infections	India India	Burning acidic seed ( <i>biba</i> ) in circle on abdomen Lead-containing tonics, such as <i>ghasard</i> , with lead concentration up to 1.6% Apply butter or oil to nostrils or oropharynx	
Middle East <sup>b</sup>	Lead poisoning (including encephalopathy, death)	Teething; cosmetics	Saudi Arabia Kuwait Oman	Teething powders: <i>Saooti</i> , <i>Cebagiri</i> ; Cosmetics: <i>Koh</i> ; Other: <i>Bint al dahab</i>	Teething powders or solutions without lead
	Lipoid pneumonia, bronchiectasis	Cleaning airway of newborn; treatment of respiratory infections	Saudi Arabia	Apply butter or oil to nostrils or oropharynx	Replace with saline drops
	Hypematremia (fatal)	Healthy newborn skin	Turkey	Salting infant's skin or placing salt in swaddling material before swaddling	Education regarding health risks

rapid differential diagnoses and treatment plans (see Table 69-1), and making informed decisions about child abuse (see Table 69-3).

*Cultural competency* is defined as the recognition of and appropriate response to key cultural features that affect clinical care. Providing culturally competent health care should be the goal of every physician caring for immigrant children. Box 69-2 summarizes a model of cultural competency that can be helpful in clinical encounters with patients from any cultural group.

Helpful Web-based resources for addressing the cultural issues in pediatric care include DiversityRX ([www.diversityrx.org](http://www.diversityrx.org)), the Office of Minority Health's Web site ([www.omhrc.gov](http://www.omhrc.gov)), and the University of Michigan Health System's Program for Multicultural Health ([www.med.umich.edu/multicultural/](http://www.med.umich.edu/multicultural/)).

## GROWTH AND NUTRITION

Growth abnormalities and nutritional disorders are among the most common health problems of immigrant children, particularly refugees, adoptees, and immigrants from similarly deprived backgrounds. Common nutritional disorders, such as iron deficiency, may be seen in a significant portion of some populations of immigrant children, such as young refugees. Nutritional deficiencies, such as in iron and calcium, may also increase the susceptibility of immigrant and refugee children to environmental toxins, such as lead. Other disorders, such as rickets, vitamin A deficiency, and iodine deficiency and goiters, may also be

quite common in some populations. More recently, concerns have been raised about vitamin D deficiency among many refugee populations and B12 deficiency among refugees from Bhutan.

With hunger and food insecurity well documented among US immigrant and refugee populations, the primary care physician must assess growth and nutritional status of immigrant and refugee children. Eligible families should be referred for nutritional support to available programs, such as The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) and subsidized school meals programs. A multivitamin with iron and minerals is likely to be beneficial for most immigrant children. Physicians should closely monitor nutritionally deprived children for catch-up growth (seen even in longitudinal growth in some cases) and developmental disorders, such as precocious puberty, that have been associated with rapid catch-up. Conversely, overweight may be seen in some immigrant populations, reflecting socioeconomic conditions and lifestyles in countries of origin that range from the formerly socialist countries of Eastern Europe to the urban environments of Sub-Saharan Africa.

All immigrant children should have complete blood counts performed, and those younger than 17 years old should have their blood lead levels evaluated. Children born outside the United States are more likely to have elevated blood lead levels than US-born children. Because a risk of acquiring elevated blood lead after arrival in the United States has been documented

### BOX 69-2 Model for Cultural Competency in Health Care

1. Normative cultural values
  - Identify values that affect care.
  - Accommodate for these values in clinical encounter.
2. Language issues
  - Use interpreter services unless fluent in patient's primary language.
  - Follow guidelines for effective interpreter use.
  - Encourage efforts to increase foreign language skills of staff and English skills of patients who are LEP.
3. Folk illnesses
  - Recognize those that may affect clinical care.
  - Suggest alternatives to harmful folk remedies.
  - Accommodate nonjudgmentally into clinical encounter.
  - Integrate into biomedical treatment plan whenever possible.
4. Parent and patient beliefs
  - Identify beliefs that may affect clinical care.
  - Suggest alternatives to harmful home remedies.
  - Carefully explain etiology and treatment rationale for given biomedical condition.
5. Provider practices
  - Maintain vigilance for ethnic disparities in screening, prescriptions, procedures, and outcomes.
  - When disparities occur, determine problem's source and address practices that might be responsible.

From Flores G, Abreu M, Schwartz I, et al. The importance of language and culture in pediatric care: case studies from the Latino community. *J Pediatrics*. 2000;137:842–848, with permission from Elsevier.

among refugees, testing should be repeated after 90 days. This testing is appropriate even in parts of the United States that generally do not have significant environmental lead contamination. Regardless of the region in the United States, new American children face the unknown risk posed by the use of traditional medicines, lead-contaminated foods and cookware, and other culturally specific practices that may expose children of many different immigrant populations to lead. These types of exposures for immigrant children have been documented repeatedly over the years in the *Morbidity and Mortality Weekly Report*. The Centers for Disease Control and Prevention's (CDC) Web site ([www.cdc.gov/nceh/lead/](http://www.cdc.gov/nceh/lead/)) contains information about lead poisoning among refugee and immigrant children. Because of the particularly high risk of elevated lead levels in refugee children, the CDC recommends testing all refugee children younger than 17 years.

## ORAL HEALTH

A high prevalence of dental caries has been documented among immigrant and refugee children. Many immigrants will lack experience with preventive oral health measures, including topical fluoride and water

fluoridation, and face significant barriers to care in the United States. Research on the association of acculturation with oral-health practices among refugees and immigrants has demonstrated that the many LEP immigrants adopt American lifestyle behaviors that are associated with poor oral health outcomes while giving up protective behaviors from their home countries. Because of LEP and partial acculturation, however, these immigrants do not fully adopt Western preventive oral health practices.

The primary care physician can play an important role in promoting healthy personal oral hygiene practices and supporting traditional customs and related behaviors (eg, breastfeeding, diets low in refined sugar, and use of chewing sticks with antimicrobial properties) that may provide oral health, nutritional, and other benefits to the child while also promoting proven oral hygiene practices in the United States (eg, ensuring consumption of fluoridated water or oral supplementation, use of fluoride-containing toothpaste). The primary care physician should conduct periodic oral health risk assessments, provide dietary counseling on limiting sugary food, assess all sources of fluoride exposure, and facilitate the establishment of a dental home by 6–12 months of age for low-income and other high-risk children and 12 months of age for all children. Application of fluoride varnish in the primary care setting should be conducted for children with no access to a dental home and those with moderate or high caries-risk until a dental home is established. In addition, in some practice settings, the targeted use of fluoride varnish for low income and other high risk immigrant and refugee children is warranted.

## BEHAVIORAL HEALTH AND FUNCTIONAL HEALTH SCREENING

Mental health and behavioral problems are common among immigrant and refugee children, in part, because many such families experience traumas. Prior violence exposure in the country of origin, ongoing exposure to violence in their neighborhoods in the United States, and migration-related stress increase the risk for posttraumatic stress disorder, adjustment disorder, depression, and other mood disorders in immigrants. In a large meta-analysis of studies of internationally adopted children, researchers found an elevated prevalence of behavioral problems and use of mental health services compared to nonadopted children. Behavioral disorders among traumatized immigrant families may be difficult to diagnose and treat in primary care settings. Even in situations in which parents identify behavioral symptoms in their children, parents may be reluctant to have children treated for behavioral disorders because of cultural beliefs or concerns about immigration status. Cultural factors may present similar challenges for diagnosing and treating behavioral disorders among nontraumatized children as well. Many immigrants and refugee families will visit their physicians with symptoms or complaints such as headache or stomachache because of underlying behavioral or emotional problems or somatization.

Somatization is common in many cultures around the world. Studies have documented the high prevalence of somatization and its association with increased clinic visits in immigrant and refugee communities in the United States. Caring for patients with somatization may be challenging. The physician's validation of the impairment from somatic symptoms and focus on functional improvement, however, may facilitate the establishment of trust necessary for uncovering the emotional basis for the symptoms. In the setting of pediatric primary care, the physician may find simple screening instruments, such as the Pediatric Symptom Checklist ([www2.massgeneral.org/allpsych/psc/psc\\_home.htm](http://www2.massgeneral.org/allpsych/psc/psc_home.htm)) or the Child Health Questionnaire ([www.healthact.com](http://www.healthact.com)), helpful in documenting functional impairment from somatization and behavioral-health problems, although language and literacy barriers can be problematic with immigrant and refugee communities. Such screening may obviate the need for disease-specific diagnostic questionnaires that are either too lengthy for practical use or may be emotionally upsetting to patients and families. Resources and online training for primary care physicians wishing to work with traumatized immigrants (or any patients who are survivors of significant violence) are also available from the Harvard Program in Refugee Trauma ([www.hprrt-cambridge.org](http://www.hprrt-cambridge.org)). A child-specific resource available to help pediatricians handle mental health issues is the Refugee Services Toolkit (RST) designed by the Children's Hospital Center for Refugee Trauma and Resilience ([www.chcrrt.org/toolkit/](http://www.chcrrt.org/toolkit/)). The RST is a Web-based tool designed to help providers understand the experience of refugee children and families, identify the needs associated with their mental health, and ensure that they are connected with the most appropriate available interventions.

## SCREENING TESTS FOR INFECTIOUS DISEASES

### Parasitic Infections

Many important diseases have nearly worldwide distributions and high prevalence among immigrant and refugee populations. When considering laboratory testing, the physician must weigh the degree of risk posed by the condition to the patient (including its level of acuity), the patient's insurance status, and the prevalence of the condition among populations from the geographic origin of the patient. For example, stool microscopy for ova and parasites will be indicated for many immigrants; however, physicians might consider ordering only fluorescent antibody staining or stool antigen testing for *Giardia* for patients from the formerly socialist, industrialized countries of Eastern Europe in which the risk of helminth infection is quite low. Additionally, the peripheral eosinophil count is a simple test that can give the physician insight into the possibility of invasive parasite infections that may not be detected in stool specimens.

For patients from tropical climates in which the risk of helminths is high, empiric treatment with albendazole has been shown to be cost effective and is used overseas by the CDC for refugees. The CDC has also recommended empiric treatment of some African

refugee populations (Southern Sudanese and Somali Bantu) for strongyloidiasis and schistosomiasis ([www.cdc.gov/immigrantrefugeehealth/index.html](http://www.cdc.gov/immigrantrefugeehealth/index.html)) and is phasing in more extensive antihelminth empiric treatment overseas. Empiric treatment for helminths, strongyloides, and *Schistosoma* infection can be accomplished in a single day with 1 oral dose of albendazole, 1 dose of ivermectin, and 2 doses of praziquantel. Because of a rare but potentially life-threatening side effect of ivermectin when used in patients with *Loa loa* infection, an alternate regimen for African immigrants from regions with endemic loiasis includes albendazole twice per day for 3 to 7 days and praziquantel as described previously. Empiric therapy with albendazole is contraindicated in children less than 1 year old, ivermectin is contraindicated in children weighing less than 15 kilograms, or less than 90 centimeters in height, and praziquantel is contraindicated in children younger than 4 years old. Increasing concerns about the high prevalence of strongyloidiasis in refugees and immigrants from tropical regions make empiric treatment a favored option in lieu of testing.

### Malaria

Recent literature has documented a high prevalence of malaria parasitemia among recent refugee arrivals from Africa. Among symptomatic cases, the triad of fever, splenomegaly, and thrombocytopenia were highly specific for malaria. Of note, a fairly high proportion of children with malaria was asymptomatic. In the report by Maroushek et al, 29% of children with malaria were asymptomatic. Because of the predominance of *Plasmodium falciparum* in most of Africa, individuals often will develop some immunity over time, thus reducing symptoms. Such is not the case with other forms of malaria that predominate in other parts of the world, particularly in Southeast Asia. As for helminths, the CDC is expanding and updating predeparture empiric treatment for malaria among refugees overseas. Newer protocols expand the use of such treatment and also switch from the use of sulfadoxine and pyrimethamine to newer artemisinin-based combination therapy, such as artemether-lumefantrine or amodiaquine-artesunate.

Primary care physicians should consider malaria testing of all refugees and immigrants from Sub-Saharan Africa and those from any malaria-endemic country who exhibit symptoms suggestive of malaria. Physicians should test liberally, given that the Maroushek study found that no symptom, either alone or in combination with other symptoms, was predictive of the presence or absence of malaria. Guidelines for treatment of malaria, including criteria for determining severity level and eligibility for outpatient treatment, are available from the CDC ([www.cdc.gov/malaria/diagnosis\\_treatment/index.html](http://www.cdc.gov/malaria/diagnosis_treatment/index.html)). In addition, 24-hour consultation is available from the CDC at 770-488-7788 during weekday business hours and by page at 770-488-7100 after hours and on weekends and holidays.

### Tuberculosis

Finally, tuberculosis (TB) infection is a major health issue for immigrant children. The foreign-born population increasingly comprises a disproportionate share of cases of active TB infection in the United States,

accounting for almost 60% of tuberculosis cases in the United States in 2008, and with a case incidence closer to that of their country of origin for the first 5 years in the United States. Children, particularly younger children, are usually in the early stages of latent TB infection, with high likelihood of progression to active disease. All immigrant children from developing and formerly socialist countries should have tuberculin skin testing (TST). If the child is significantly malnourished or immunocompromised, then the physician should consider placing control tests (eg, *Candida* antigen) as well. Prior bacille Calmette-Guerin (BCG) vaccination is not a contraindication to tuberculin skin testing. Internationally-adopted children should receive tuberculin skin testing immediately post-adoption and 6 months later. As an alternative, interferon-gamma release assay (IGRA) testing may be used in place of TST to detect tuberculosis in children over 5 years old. IGRA may be preferable to TST in children over 5 years old with previous BCG vaccination.

Other highly prevalent infectious diseases that may warrant screening tests include hepatitis B, hepatitis C, HIV, syphilis (both congenital and sexually acquired), and other sexually transmitted infections. In particular, HIV testing of refugees is no longer required prior to admission to the United States; however, it is recommended that all refugees be tested for HIV. Additionally, some refugee and internationally-adopted children may be unimmunized or under-immunized for common diseases such as hepatitis B. Immigrants and refugees from areas with endemic hepatitis B, such as Asia and Africa, should be screened with HBsAg and anti-HBs within a few weeks of arrival and again 6 months later. Children with negative serologies should be given the appropriate immunization schedule, and those with positive serologies should receive appropriate follow-up and management. Physicians, again, should weigh individual and geographic risk, as well as the expense and benefits for the patient, when considering such testing.

## IMMUNIZATIONS AND SEROLOGIC TESTING

A safe presumption is that very few immigrant or refugee children seen as new patients in a pediatric practice will be up to date with US vaccine standards set by the CDC Advisory Committee on Immunization Practices (ACIP) (see [www.cdc.gov/vaccines/](http://www.cdc.gov/vaccines/)). Such is the case simply because newer vaccines used commonly in the United States are not available or used in most other countries. Examples include vaccines for *Haemophilus influenzae*, pneumococcus, human papillomavirus, and varicella. In addition, many immigrants will not have adequate documentation of past vaccines. In some cases, documents may actually be fraudulent. Common problems include incomplete or inaccurate documentation of vaccine records, receipt of vaccines at unacceptable intervals or times, and poor immune response as a result of malnutrition. The public health imperative for completing immunization is also illustrated by recent outbreaks of imported measles in Indiana and Boston, the multistate mumps outbreak in the Midwest, and

congenital rubella syndrome in a refugee infant born in New Hampshire. Regarding measles, mumps, and rubella, physicians should be alert when reviewing records to receipt of vaccines with only 1 or 2 components and receipt of measles vaccine before the first birthday, as recommended by the World Health Organization for countries with endemic measles but not considered a valid dose by ACIP.

Immunization should be a priority for new immigrant children who may have school enrollment delayed pending completion of immunizations. Similarly, immunization with a multi-dose series for highly prevalent disease antigens, such as hepatitis B in some populations, should not be delayed pending serologic testing. If immune (either from naturally-acquired infection or a completed primary vaccine series), further doses are not needed. Refugees with partial series but positive serologic tests of immunity still should finish the primary series.

For younger children, physicians should begin primary or catch-up immunization according to ACIP schedules. For school-aged children and adolescents who have insurance coverage, physicians may choose a mixture of immunization and serologic testing for immunity to satisfy school and other requirements for proof of immunity. Studies of serotesting among refugees and immigrants have documented high levels of immunity to some diseases such as hepatitis B, varicella, measles, and rubella. In the case of varicella, serotesting before immunization is a cost-effective strategy. Typically, seroprevalence will increase throughout childhood, with large increases at 1 year old (for measles in particular) and at school age. By early adolescence, most immigrants will have either naturally acquired immunity or prior immunization for these diseases, except for hepatitis B, which will reflect the level of endemicity in the immigrant's country of origin. For hepatitis A vaccine, recommended for universal immunization by ACIP in 2006, most immigrants will have naturally acquired immunity if they lived in endemic regions until school age.

## CONCLUSION

Primary care physicians caring for children new to the United States serve an important role as the gateway to the medical home. Language and cultural divides that separate physician from patient may be bridged by providing access to language services for LEP patients and ensuring the delivery of culturally competent care. At the same time, physicians should be attentive to the acute and chronic health issues specific to immigrant children and their families. Foreign-born children and children of immigrants may continue to encounter significant challenges to their health and well-being due to the numerous cultural, linguistic, and legal barriers to accessing services discussed in this chapter. Immigrant children and adolescents may experience significant stress, anxiety, and depression related to issues of acculturation and immigration. LEP children attending schools with limited experience with this population may have academic difficulties related to English proficiency

that may be mistaken for pathology, such as learning disabilities or developmental delay. These children therefore may need continued follow-up in primary care to discuss school progress and related issues.

Primary care physicians should work to anticipate and integrate potential health and development issues into the health screening and long-term care of immigrant families. By effectively screening for and treating these issues and promoting wellness with cultural sensitivity, the primary care physician can create strong bonds with immigrant families and communities and ensure that immigrant children receive the highest quality pediatric primary care with high levels of patient and parent satisfaction.

## Chapter 70 ADOPTION

Sarah H. Springer, MD

## WHO ARE THE CHILDREN?

Most children adopted in the United States today are not adopted as newborns. With easy availability of family planning and general acceptance of single motherhood, fewer newborns are placed for adoption than in generations past. Instead, most adopted children join their families after being in the domestic child welfare system or in foster or institutional care overseas. Many children with medical or developmental disabilities who were, in previous times, considered unadoptable are now being successfully placed with adoptive families. Today, adopted children come with a history of life before their adoption, and this history has a tremendous effect on their needs and outcomes, both in the short term and over time.

Some children adopted from the domestic foster care system come to their adoptive families as infants, placed first as foster children, then later adopted by their foster parents. These children have the benefits of nurturing care from infancy but may still experience the long-term sequelae of prenatal adversity, particularly substance exposure. More commonly,

children adopted from foster care are older and have experienced significant abuse and neglect before adoption. Their long-term physical, mental, developmental, and behavioral health risks and needs are determined by the specifics of these insults, but are frequently complex. (See Chapter 72, Children in Foster or Kinship Care.)

Child care circumstances vary tremendously among the countries from which children are adopted internationally. Some children are cared for in high-quality, family-setting foster care, whereas others are cared for in institutional settings that can vary from small group homes with reasonable resources to large, extremely resource-poor orphanages. Some children enter care as newborns because of poverty, social adversity, or political circumstances; others enter as older children after experiencing the same sorts of abuse and neglect that place children into the foster care system in the United States.

More international children than ever before are being adopted with identified special health needs. These can range from fairly simple problems such as orthopedic deformities, isolated cleft lip and palate, or ventricular septal defects, to chronic infectious illnesses such as hepatitis B and HIV, or complex syndromes with multiple medical and developmental disabilities. Health care for these needs may or may not have been available before adoption, and medical procedures may have been traumatic for the child who experienced them without the love or support of a parent.

With or without identified special needs, most children are at least older infants or toddlers before they are eligible for international adoptive placement. Knowing how and why a child came into care is important, as is knowing the type of care a child experienced, because the history before adoption often sheds light on the physical, mental, and developmental health issues a child might be expected to face immediately and over the long term.

Children come to the United States from many countries through adoption. Although some countries have sent substantial numbers of children for many years, the list of sending countries is continually changing as a result of political and social circumstances both in the United States and abroad. The US State Department listing of orphan visas issued provides a concise listing of the numbers of children adopted from the top 20 countries of origin each year. The circumstances of individual children available in each country are varied, but general considerations are listed in Table 70-1 for the current top 10 countries of origin.

Other common adoptions today include kinship placements and second-parent or coparent adoptions. Current child welfare practice emphasizes finding permanency for children more quickly than in the past and keeping children within their communities and cultures of origin whenever possible. Estimates indicate that approximately 200,000 children, or approximately one-third of those in foster care, are placed in foster care with extended family members. If they are not able to return to the custody of their birth parents, then many of these children are adopted by their

extended family members or cared for in permanent legal guardianship relationships. This approach allows children to maintain family connections but can pose unique challenges to the adopting parents, who must negotiate complicated relationships among the children, the birth parents, and other extended family members. Second-parent adoptions refer to the adoption of a child who already has one legal parent by the spouse or partner of that parent. Coparent adoption is the adoption of a child by 2 unmarried adults, often gay or lesbian partners.

## ADOPTION PROCESS

Pediatricians can be most helpful to adopting parents if they are knowledgeable about the processes and types of adoptions. Adoption laws vary by state, but the basic legal requirements are the same. Adopting parents must undergo a social work evaluation (commonly referred to as the *homestudy*) to verify that they are minimally fit to be parents, have minimal resources to support a child, and do not have records of child abuse or significant criminal records. Families do not have to be wealthy or highly educated, but simply have to prove that they would be able to love and nurture a child. The homestudy must typically be provided by a social worker licensed to work in a particular state, who produces a written document verifying the adults' suitability for parenthood, which becomes part of the legal record of the adoption. Families adopting across state lines must satisfy the requirements of both states, and families adopting internationally must meet all requirements of the state and federal governments and those of the child's birth country.

Adoption placements can be arranged and carried out by licensed agencies or independent facilitators, depending on the laws of individual states and countries. Adoption agencies may be public agencies acting as an arm of the public child welfare system or may be licensed private agencies. Facilitators may be of any training background but are commonly social workers or attorneys who specialize in connecting would-be adoptive parents with available children. For international adoptions, most countries of origin require that their children be placed by a licensed nonprofit agency. In addition, the Hague Convention on Intercountry Adoption (a multinational treaty that was signed by the United States in 1994 and entered into force in 2008) requires that all child placements between participating countries be governed by a strict set of ethical guidelines and be carried out by licensed and accredited agencies that have enforceable government oversight. Approximately 80 countries have signed on to the convention so far, meaning that adoptions between these countries must meet ethical and procedural guidelines that provide greater protections for children, birth parents, and adopting parents.

Families adopting newborns are often in touch with the child's birth parents before the adoption because most birth parents today participate in the choosing of their child's adoptive parents. Many adoptive parents travel to be at their child's delivery and often participate in ongoing, open relationships with the child's birth parents. Some adoptions are finalized very

**Table 70-1** Top Ten Countries of Origin of Internationally Adopted Children (2009)

COUNTRY	PREDOMINANT AGE AND GENDER	REASONS IN CARE <sup>a</sup>	TYPE OF CARE	AVAILABILITY AND RELIABILITY OF RECORDS <sup>b</sup>	COMMON HEALTH CONCERNS <sup>c</sup>
China	Girls—infants to teens and older boys with special health care needs	One-child policy or social need for male children	Mostly institutional; some foster care	Minimal—sometimes more information available for children with physical disabilities; reliability variable	Lead intoxication, dental enamel insufficiency
Ethiopia	Boys and girls—infants and older	Children orphaned by parental death from HIV infection	Institutional	Variable quality. Laboratory studies from Addis Ababa usually reliable	Prenatal HIV exposure, profound malnutrition
South Korea	Boys and girls—infants and older	Lack of social acceptance of single parenthood	Foster care	Usually detailed records, very reliable	—
Ukraine	Boys and girls—toddlers and older	—	Institutional	Minimal	Prenatal alcohol exposure
Vietnam	Boys and girls—infants and older	—	Institutional	Variable quantity and reliability	
Haiti	Boys and girls—toddlers and older	—	Institutional	Limited information, variable reliability	Profound malnutrition
India	Boys and girls—infants and older	—	Institutional	Often very detailed records, usually fairly reliable	
Kazakhstan	Boys and girls—toddlers and older	—	Institutional	Minimal	Prenatal alcohol exposure

<sup>a</sup>The reasons children are eligible for adoption in all countries can include severe poverty, social adversity (maternal drug or alcohol addiction, incarceration, homelessness, mental health disabilities), and child abuse and neglect, with government termination of parental rights. The *Reasons in Care* column lists additional factors common to the country.

<sup>b</sup>Availability of reliable records does not mean that recommended new-arrival testing can be eliminated, but rather that preadoptive parents can feel reasonably confident that the information they have will accurately reflect the history of the child they are bringing home.

<sup>c</sup>The Common Health Concerns column is not an all-inclusive list, but rather a note of conditions that are even more common for children from that country than for all international adoptees.

quickly, whereas others take significantly longer, depending on the laws of the state where the child was born and of the state where the adoptive parent or parents live. Financial costs for domestic newborn adoptions are extremely variable, but can be significant when all of the individual services performed are tallied. Costs may include legal and social work fees, travel expenses, and, in some states, payment of room and board or health care expenses for the birth mother before the delivery.

Families adopting children from the child welfare system may have the child in foster care from birth, but only become eligible to adopt after the child's birth parents are unable to resume custody. Other children come into the child welfare system later after experiencing abuse or neglect. If birth parent rights are later terminated (see Chapter 72, Children in Foster or Kinship Care), then the child may be adopted by the child's foster parents or by another family. Adoptive families have ongoing contact with birth parents less frequently in this kind of adoption, although some adoptions, especially kinship placements, do maintain ongoing contact with birth parents. Many of the children who are waiting in the child welfare system for

adoptive families are older, are part of sibling groups, and have significant psychological scars from their earlier life experiences. Families rarely have to travel to adopt from the public system because most communities have more children in care who are in need of permanent homes than families waiting to adopt them. Adoptions from the public child welfare system are often finalized months, or even years, after the child is placed in the home as due process is carried out to protect the rights of birth parents. Financial costs for this type of adoption are typically much more modest, with many of the services provided free of charge to the adopting family by the public agency, its mission being to find the best home for each child on behalf of the state or local government.

Parents adopting internationally most often travel to adopt their child, with adoptions from some countries requiring 2 or 3 trips. Although this process can be stressful and financially costly, it offers adopting parents the opportunity to get to know the people and culture of their child's birth country. In addition to a valid homestudy, families are required to pass criminal record clearance from the Federal Bureau of Investigation, document that the child meets the US definition

of an adoptable orphan, and complete immigration paperwork for the child. Families adopting from Hague Convention countries must also complete at least 10 hours of training on the needs of internationally adopted children, and the child must be deemed eligible for international placement by the sending country after reasonable efforts to place the child in country have been documented.

On finalization of the adoption by US citizen parents, the child is automatically granted US citizenship, although parents must complete yet more paperwork to claim this legal status. It is critical that parents complete this process in order to ensure the child's full legal rights as a US citizen.

## ROLES OF THE PEDIATRICIAN IN PREADoption CARE

Unless the physician has a special interest in adoption medicine, a family adopting its first child might not meet the physician until the parent or parents receive information about a specific child or even until the child is home with the parents. Most pediatricians, however, will have families already in their practice who decide to adopt, and these physicians can play an important role in helping the entire process to be a success. Pediatricians should be familiar with common adoption concerns and can contact members of the American Academy of Pediatrics (AAP) Council on Foster Care, Adoption, and Kinship Care for help.

Parents who are wondering what type of adoption to pursue should consider the potential needs of the children. By looking at the intersection of 3 variables, families and their physicians can anticipate at least some of the needs a child might be expected to have and some of the adoption process issues.

First, families need to consider the age of a child: children beyond infancy bring with them psychological, physical, and social consequences from previous circumstances. Professional mental health services may be needed to allow a child to reach full potential, in addition to developmental and educational supports. The second variable is whether a child is of the same or another race as the adopting parent or parents. The third variable is whether the child is in the same or a different country or culture. Although transracial adoption is not associated with poor outcomes, helping a child develop a strong sense of racial and cultural identity is important to the child's self-esteem and psychological well-being and can be challenging, especially in communities with little racial or cultural diversity.

Parents may also request help in deciding on an agency or facilitator to conduct the adoption. In general, parents should be encouraged to use agencies that are licensed (and, therefore, subject to minimal ethical and practice standards) with a mission to promote the welfare of children. Agencies with the mission of finding the right family for each child often cost more and require more of adopting parents, but will also provide appropriate education and long-term support for families. Agencies with the mission of conducting an adoption rapidly may seem appealing at first glance, but often do not share the complexities

or risks of the children with adopting parents and are rarely there for long-term support.

Pediatricians may also be asked to review the information a family receives about a particular child whom they are considering adopting. Reviewing this information with a family is not to screen out children, but rather to help the prospective family understand the information given to them, know what additional information they need to gather, and then make a well-informed decision as to their ability to be the best parents for the child, given the predictable needs or risks. This service is often best performed by physicians familiar with all the types of adoptions, the information available for children coming from different countries, and the common risks seen in different groups of available children. Many agencies provide families with lists of physicians specializing in adoption medicine, and these can also be found through the AAP Council on Foster Care, Adoption, and Kinship Care Web site.

Finally, pediatricians need to know the infectious disease and travel health issues involved for families traveling internationally to adopt. Even family members who are not traveling, but who will be in close household contact with the newly arrived child, can be affected and need to be protected. Recent increases in the numbers of older children and children from countries with endemic hepatitis A have resulted in numerous cases of hepatitis A being spread to family members, whose risk for hepatitis A is more than 100 times greater than that of the general population. There have been several outbreaks of measles as well, spreading from newly adopted children infected at the time of travel to both family members and other travelers on airplanes. Parents should be counseled early on to review and update the immunizations of all family members before they travel to adopt; this includes hepatitis A, hepatitis B, Tdap (tetanus, diphtheria, and pertussis), and seasonal influenza vaccines, all of which many adults have never received. Parents will also need to plan for any chronic health needs of their own, bringing an ample supply of necessary medications in carry-on luggage. Families adopting a child with special medical needs will need to plan for those as well, bringing items such as cleft palate bottles, and learning relevant clinical warning signs, such as those of congestive heart failure when adopting a child with congenital heart disease.

Families should also be advised to follow strict food and water precautions, to prepare a travel first-aid kit, and to have emergency health contact information for themselves, their new child, and any other family members who are traveling. Families traveling to very remote locations or very impoverished countries may need to bring antibiotics or other medications for themselves and their new child, given that medical care may be difficult or impossible to obtain. Educating the family that antibiotics are being prescribed without seeing the child only for this unusual circumstance can help prevent inappropriate expectations later. Physicians should provide a means for families to contact them in an emergency and written directions as to when and under what circumstances

they might consider using the medications they are carrying.

## NEW-ARRIVAL ISSUES

### Social and Emotional Issues

The arrival of a newly adopted child into a family brings joys and stresses similar to those that accompany the birth of a child. In addition, however, all of the circumstances that led to the adoption must be managed by adopting parents, birth parents, siblings, extended family, and the child. Adopting parents who have experienced infertility or the loss of previous children may have unresolved grief, which can complicate the feelings of joy accompanying the arrival of this child. In addition, long waits for parenthood can create unrealistic expectations, which are often in stark contrast with the reality of parenting any child, let alone one who has lived through adversity and whose whole world has just changed. Postadoption depression is as real an entity as postpartum depression, and pediatricians should be prepared to identify and refer affected parents.

For children adopted outside of the immediate newborn period, the transition into the new adoptive family is often bewildering, frightening, and full of loss. Ideally, children should be given as much preparation as possible, with older children even participating in the decision to join a particular family. In reality, however, many children are simply taken one day from everything that is familiar and handed to strangers. Children who have been in foster care or who have developed strong attachments to orphanage caregivers will usually grieve the loss of these significant people, and older children may worry about their well-being or wonder if the caregivers are searching for them. Even children who have not been treated well by previous caregivers still have connections to them and may still grieve their loss. Adoptive parents and pediatricians need to understand this process, comfort the grieving child, and help the child develop a strong sense of connection and security with the new parents. Allowing the child to talk about the previous caregivers, to look at pictures of them, and even to telephone or write to them can help the child process this grief. Parents may need encouragement to allow children to share their grief, given that not talking about it may seem easier. Allowing children to share these strong feelings can help build strong bonds of new attachment.

All children have to adjust to the arrival of a new sibling, but an adopted sibling brings challenges that a newborn does not. Most often, the new child is not a helpless newborn, but rather a mobile, demanding competitor for not only parental time and attention, but also toys, food, and space. Extra love, understanding, and attention are in order, which can be hard to attain when the demands of the newly transitioning adoptee are high.

Extended family members also have a significant effect on the new-arrival period. Some may be eager to shower love and attention on the bewildered, overwhelmed, grieving child, whereas others may not accept the child as a true member of the family. Sharing

information about adoption and the child's expected transition needs with extended family members before the adoption can help create a nurturing acceptance into a warm extended family without overwhelming the child.

Adopting parents should plan for plenty of quiet, uninterrupted time with their newly adopted child, regardless of the age of the child at arrival. Helping the child develop a strong attachment to the parents is of utmost importance because this groundwork is the foundation of healthy parent-child relationships and, ultimately, of all human relationships. Parents should think of their child as a newborn emotionally in an older child's body. Parents should be the ones to meet physical needs and to provide comfort so that the child learns to use them as a secure base in the world. Some parents are granted parenting leave by employers, whereas others must fight for it, given that many employers finance parenting leave through medical disability coverage, which does not apply when a woman has not given birth. Pediatricians should work with parents to convince employers that time at home with their newly adopted child is vital to the child's long-term physical and emotional health, and parents should be encouraged to use as much leave time as possible.

### Medical Issues

The most important considerations in planning a child's postadoption medical evaluation are the risks inherent to the child's previous circumstances. Whether the child was adopted domestically as a newborn, from the foster care system, or internationally, the social and medical risk factors of the child's birth parents and prior circumstances should guide medical and developmental assessments.

Parents adopting newborns domestically may receive extensive records on the child, birth parents, and extended biologic family, or they may receive nothing at all. Pediatricians should assess not only the available extended family medical history, but also the birth parent social history, paying special attention to risk factors for adverse outcomes for the fetus and child, including issues such as alcohol or other drug use during pregnancy, high-risk sexual behavior, and domestic violence. Records of birth mother prenatal testing for infectious diseases may or may not be available or reliable. Unknown or missing information, including unknown birth father information, should be presumed to be high risk. Decisions regarding testing for HIV, hepatitis B and C, syphilis, and other perinatally transmissible diseases should be made on an individual basis after considering the available information. Testing may need to be repeated after the child is 6 months old, to rule out late-term infection, depending on the specific history and available birth mother test results.

Children adopted from the foster care system have, by definition, experienced significant abuse or neglect and are at high risk for long-term mental health and developmental sequelae. They are also at very high risk for infectious exposures and malnutrition, dental problems, and physical health needs resulting from previous trauma. (See Chapter 72, Children in Foster

or Kinship Care.) Medical evaluation of these risks should be guided by available records, with unknown or missing information being assumed to be high risk.

Children adopted from overseas have most often been cared for in institutional settings, where infectious diseases, including many which may not be obvious on physical examination, are easily spread. In addition, significant infectious and environmental health risks often exist in sending countries, but are unfamiliar to physicians in the United States. These must be remembered especially in the differential diagnosis of febrile, neurologic, or gastrointestinal symptoms, not only at the time of arrival but also for several years afterward. Nutrition is rarely adequate for children in institutional care, making macronutrient and micronutrient deficiencies common. Because a specific, detailed, reliable history is rarely available for a given child, the medical evaluation must be based on known significant risks, rather than individual history.

All newly arrived international adoptees should have a detailed, thorough evaluation soon after arrival, including assessment of overall health, nutritional status, developmental delays, psychosocial adjustments, hearing and vision, and laboratory studies to assess for infectious diseases, nutritional deficiencies, and toxin exposures. Medical records from the child's country of origin should be reviewed but can rarely be taken as guaranteed truth, given that record-keeping, transfer, and translation systems are notoriously unreliable and cannot be verified (see Table 70-1).

As outlined in the AAP *Red Book*, laboratory studies for all internationally adopted children should include at least hepatitis B (surface antibody, surface antigen, and core antibody), HIV, syphilis, stool for parasites, and tuberculosis testing. Most children (especially those adopted from Eastern Europe or Asia and children whose birth parents were intravenous drug abusers) should also be tested for hepatitis C. Prior Bacille Calmette-Guérin (BCG) vaccination is *not* a contraindication to purified protein derivative (PPD) testing, and *all* internationally adopted children fall into at least the moderate-risk category when interpreting PPD test results. Children older than 2 years of age who are adopted under the Hague Convention on International Adoption (see Adoption Process) may have a PPD placed and read by a US Embassy panel physician before being granted a visa to enter the United States. When parents have documentation of the PPD being given and being read, this PPD can "count" and does not need to be repeated again just a few weeks later. All of these infections can be completely asymptomatic but have significant individual, family, and public health implications if left undetected and untreated.

Deciding what to do about a child's immunizations can be challenging. If no written records are available, then a new series should be initiated according to the consensus catch-up schedule, given that even strongly positive antibody titers cannot, at one point in time, guarantee a steady-state level of immune protection. Although considerable controversy and ongoing research exist on this question, written records generally cannot be taken at face value because whether the

child received the injection cannot be verified, nor can the storage or handling of the vaccines be verified, given that orphanages around the world frequently receive old, outdated vaccine supplies. Records should be reviewed carefully, with attention to the timing of doses and the appearance of the records. For example, is it an original, with tattered edges and different inks, or a pristine, brand new copy? Are there doses given before the child was born? Are the vaccines stated available in the sending country? When records seem legitimate and show vaccine timing that meets the guidelines provided by the AAP and the Advisory Committee on Immunization Practices, titers can be checked, and, if positive, these doses can then be counted for the child, with any remaining doses or missing vaccines following the *Red Book* catch-up schedule. Children older than 2 years of age who are adopted under the Hague Convention on International Adoption (see Adoption Process) may receive vaccines by a US Embassy panel physician before they travel home with their new parents. Parents are usually given records of exactly what the child received, and proper storage of these vaccines is guaranteed by the US Embassy. Unfortunately, however, receiving these doses effectively takes away the option of checking titers to verify doses given while the child was in the orphanage because serial titers would be required to prove that immunity shortly after arriving home is long lasting. Doses given at the US Embassy can be "counted" as the first dose of each vaccine, and the series can be completed from there according to the consensus catch-up schedule.

Nutritional deficiencies also are common, with the diet of most children before their international adoption being inadequate in overall calories, protein, and micronutrients. Most children are at least mildly malnourished at the time of adoption, as demonstrated by the rapid catch-up growth of even those who are on the growth curve at the time of adoption. Some children are well below the first percentile for birth weight and height. Most often, this circumstance is the result of combined malnutrition and profound social and emotional neglect, but hypothyroidism must be ruled out, as must true growth hormone insufficiency, if rapid catch-up growth does not occur. Laboratory evaluation should include a complete blood cell count to assess for iron deficiency and calcium, phosphorus, and alkaline phosphatase assessments for rickets. Hemoglobin electrophoresis should be included in follow-up for any child who has microcytic anemia, especially a child from Asia or Africa. Thyroid function tests should be obtained for children with significant growth or developmental delays. Lead intoxication is also common, especially in children adopted from China, and all children should have serum lead levels checked. Box 70-1 highlights components of the medical evaluation of newly internationally adopted children.

All newly adopted children, regardless of the type of adoption, should have a thorough assessment of development, including hearing and vision. For newborns, this assessment will be the same as for any other routine well child care, with special attention to any known long-term risk factors. Children

**BOX 70-1 Medical Evaluation of New Internationally Adopted Children**

On arrival, *all* children should have the following:

- Thorough physical examination
- Purified protein derivative test (PPD) (may need to alter timing if child received Bacille Calmette-Guérin [BCG] vaccination within the previous several months or received repeated, recent PPD tests)
- Hepatitis B surface antigen, surface antibody, and core antibody testing
- Human immunodeficiency virus (HIV)-I and -II enzyme-linked immunosorbent assay (ELISA) (consider DNA polymerase chain reaction in infants)
- Assessment for syphilis—nontreponemal testing (rapid plasma reagin or Venereal Disease Research Laboratory test) for all adoptees. Treponemal testing (microhemagglutinin *Treponema pallidum* or fluorescent treponemal antibody absorbed) if history of exposure or positive nontreponemal test results
- Assessment of stool for ova and parasites (3 samples taken at least 48 hours apart)
- Complete blood cell count
- Lead level testing
- Assessment for rickets: calcium, phosphorus, and alkaline phosphatase
- Detailed review of immunization status, with testing as needed to confirm immunity
- Detailed developmental assessment
- Assessment of hearing and vision

On arrival, risks should be assessed and the following checked appropriately:

- Hepatitis C ELISA for all children from Eastern Europe or Asia or those with history of risk factors
- Thyroid function test for children with significant growth or developmental delays
- Hemoglobin electrophoresis for children from Africa or Asia who have microcytic anemia
- Stool bacterial infection assessment for children with diarrhea or other gastrointestinal symptoms
- Stool testing for *Strongyloides* and *Schistosoma* spp for children from endemic regions who have unexplained eosinophilia
- Serologic testing for *Trypanosoma cruzi* for children from endemic countries in South and Central America
- Thick and thin blood films for malaria for febrile children from endemic areas

Six months after arrival, *all* children should have the following:

- PPD test
- Hepatitis B surface antigen, surface antibody, and core antibody testing
- HIV-I and -II ELISA
- Hepatitis C ELISA (for previously identified risk groups)

adopted after the newborn period should have a careful assessment of all domains of development soon after placement. Most children make rapid developmental progress after they are in a nurturing family environment. Children whose delays are profound or persist beyond the first 2 to 3 months should be referred to formal developmental support services.

Many children have significant medical needs on their arrival to their new families, some of which are known before the adoption, and some of which will be revealed by the new-arrival evaluation. Further diagnostic workup and treatment of these medical needs should be planned carefully, balancing medical urgency with the child and family's need for quiet nesting time in the early days of the adoption. Simple treatments, such as antibiotics or iron supplements, can begin right away. Potentially transmissible infections, such as intestinal parasites, hepatitis, and tuberculosis, should also be treated quickly. Urgent, time-sensitive, or potentially life-threatening medical conditions must be treated immediately (eg, congestive heart failure, dehydration, extremely high lead levels, untreated syphilis, dense cataracts). Treatment

of nonurgent medical concerns, however, can and should be deferred until the family has had some time together and the child has begun to learn to use the parents for comfort and support. Common problems in this category include repair of cleft lip and palate, orthopedic conditions, congenital heart defects, dental work, and strabismus surgery. Truly elective procedures, such as circumcision or repair of minor anomalies, should always be deferred until the child has developed a secure bond with the new family.

### First Year Home

The first months in the adoptive home represent a transition time for the adopted child and the rest of the family, during which the groundwork is laid for the long-term success of the adoption. Regardless of age, the child should be seen at least several times over the first year home to monitor catch-up in growth and development, child and family mental health needs, and the attachment of the child to the new family. In addition, all children should have age-appropriate hearing and vision screens, given that children adopted from foster care or orphanages have high rates of auditory and visual impairments. These

visits can be timed to accommodate catch-up on immunizations and follow-up of identified medical needs.

Perhaps most important, careful attention should be paid to attachment-related behaviors in newly adopted children. Children who have always had loving, nurturing care understand how to use an adult as a secure base in the world and will transfer this designation to a new parent quickly, usually within several weeks. Children who have never experienced one-on-one, emotionally attuned caregiving, however, have often learned to cope with life's hardships on their own, without relying on an adult. These children need to be overtly taught to use their new parents as their base in the world because secure attachments are the foundation of healthy long-term relationships. Parents may be impressed with the child's self-sufficiency, but they should be encouraged to intervene frequently, teaching the child to see the parent as the active provider of food, comfort, and entertainment. Pediatricians should closely monitor newly adopted children for signs of developing strong attachments. If, after several months, the child does not preferentially use the parent or parents as a source of safety, security, and joy, then the pediatrician should refer the family to a therapist experienced in attachment disturbances.

Most children adopted out of foster care or internationally have significant developmental delays at the time of placement. These delays usually resolve rapidly after the child is in the care of loving, nurturing parents; therefore, delays that persist beyond the first 2 to 3 months should be carefully evaluated. Young children learn new languages very quickly; thus, language delays that persist should not be presumed to be the result of learning a new language but rather should be carefully investigated, with early initiation of speech and language therapy. Younger children qualify in most states for early intervention services, and older children can be evaluated and treated through local school districts or privately. For internationally adopted school-aged children, having academic assessments performed in the native language can be advantageous within the first 1 to 2 months home, before fluency in that language is lost, given that full fluency in the new language may take several years.

Deciding when to start a newly adopted school-aged child in school can be difficult and needs to be an individual decision for each child, balancing the need for family bonding time with the child's academic needs and social desires. Children who have never been to or have missed substantial portions of school may need to work on academic basics typically taught to younger children, while being afforded social opportunities and enrichment classes with same-aged peers. Many children do well to start school part-time, gradually working up to full-time attendance as they develop greater comfort with all of their new surroundings. Some children do well starting at a lower grade level to be taught academic basics, and move rapidly through several grade levels as they acquire skills and catch up to their same-aged peers. School-aged international children will qualify for English as a Second Language (ESL) services, in addition to any

learning supports that they may need. Parents and pediatricians should not let schools opt out of learning supports because a child is not a native English speaker; internationally adopted school-aged children frequently have *both* learning support and second-language needs.

Most newly adopted children struggle in some way with the routines of daily living, including eating, sleeping, bathing, and toileting, among other routines. Even a child placed as a newborn may have these issues if exposures were encountered prenatally from which the child experiences withdrawal symptoms. (See Chapter 104, Prenatal Drug Use: Neonatal Effects and the Drug Withdrawal Syndrome.) Children who have not had enough food (particularly those cared for in institutional settings where, in addition to inadequate volumes, food is never available to satisfy individual hunger) often eat huge volumes of food and may hoard food, alarming parents and physicians alike. This circumstance should be recognized as an adaptive survival behavior from the prior life circumstances and should be not restricted or punished. When children are allowed unlimited access to healthy, age-appropriate food, most will learn within several months that enough is now available and that they can have it whenever they need it, and will slow down to more typical levels of intake. If, on the other hand, the child's intake is restricted, then the previously learned strategy of taking all that is available whenever it is available will continue, often developing into more secretive food-hoarding behaviors and other long-term eating disorders. Given all of the information currently targeted at parents around preventing childhood obesity, pediatricians may need to help parents understand this seemingly paradoxical advice and realize that healthy eating habits in the family will prevail after the child truly believes that there will always be enough food.

Sleep problems are obviously a common concern for all children but are almost universal among newly adopted children. Many of these children have never slept alone, in a dark room, or with any notion of safety at night, and internationally adopted children may have traveled through many time zones to arrive at their new home. Sleep deprivation quickly takes its toll on parents and children alike, complicating all of the other new-arrival transitions. Until a child has developed strong attachments to the parent or parents, however, this time is inappropriate for sleep strategies that encourage parents to leave a child alone. Until the child has thoroughly internalized the notion that the parent or parents will always be available when the child needs them, parents should be encouraged to be as physically and emotionally present at nighttime as the child needs to feel safe and secure. This task can be accomplished, however, in the child's room and bed, using the desired long-term sleep routines so that parents can wean themselves out of the child's bedtime routine as the child develops a sense of safety and security. Older children, especially those who have experienced abuse, may need explanations from parents of nighttime noises before they will feel safe enough to sleep. By balancing these short- and long-term goals from the beginning, most children

can be helped to sleep peacefully all night in their own bed within several months.

Sensory-seeking or avoiding behaviors, as well as autistic-like repetitive behaviors, are common among children who have experienced severe deprivation before adoption. As with overeating mentioned earlier, these are adaptive behaviors in a setting with little or no stimulation and usually resolve quickly when more stimulation and human interaction are made available. Many children revert to these behaviors when tired, stressed, or bored, and parents can learn to read these behaviors as cues to these feelings. Reverting to self-stimulating behaviors to cope with fatigue or stress may continue for years after adoption, with no other pathologic behavioral concerns. On the other hand, children who do not respond to nurturing parenting, but instead continue to self-stimulate regularly rather than interact with the world, should have a full developmental and behavioral evaluation.

Another common dilemma, particularly for internationally adopted children, is an uncertain date of birth. Many children come into care after being born at home, with no official record of the birth or, more commonly, after being abandoned. Assigned birthdates may or may not be accurate, particularly for older children, given that the growth and developmental delays that result from malnutrition and neglect make children seem to be younger than they really are. Older children are occasionally deliberately assigned a younger age for well-intended reasons, such as increasing the child's chances of being adopted or enabling an oldest child to remain with younger siblings. As previously reviewed, most children are significantly delayed in their growth and development on arrival, and these delays, combined with knowledge of an assigned birthday, often tempt new parents and pediatricians to consider changing the child's date of birth. Because these delays usually quickly resolve, however, the notion to consider legally changing the child's birth date in the first or second year after arrival is rarely advisable. Bone age testing or dental age assessments are not helpful early on, given that both malnutrition and neglect cause delays in bone and dental age as they do in the rest of the child's development, and thus should not be used as justification for changing a birth date. When concerns about age discrepancy persist a year or more after adoption, parents and pediatricians should carefully consider what would be gained and lost for the child if the date were to be changed. This situation is obviously more common for children adopted after the infant and toddler ages, and, as such, children should be included in the decision making about this important piece of their identity.

### Long-Term Issues

In addition to any health issues identified before or immediately after adoption, long-term health issues common to adopted children should be considered. Recognizing these risk factors in a child's history can help pediatricians maintain appropriate surveillance above and beyond the usual well child care routine and provide referrals and support proactively.

Most important, the long-term effects of early adversity cannot be forgotten. Early malnutrition, abuse, neglect, or trauma can cause significant long-term cognitive, developmental, behavioral, and mental health struggles, even after years in a warm, nurturing adoptive family. Developmental disabilities, mental health problems, and substance abuse are not uncommon factors in unplanned pregnancies or inability to care for their children in the first place, leaving adopted children as a group with a higher frequency of genetic predispositions to these diagnoses than the general population. Prenatal substance exposure, especially to alcohol, also carries significant long-term risks. Teasing out which of these factors is responsible for a given child's struggles is often difficult or impossible; but, for most adopted children, a safe assumption is that any of these predisposing issues might be a causative factor.

Many children experience significant struggles as they enter school age. Difficulties with attention and impulse control often lead to the diagnosis of attention-deficit/hyperactivity disorder (ADHD), although they frequently are far more complex. Children should have a thorough psychoeducational or neuropsychological evaluation to tease out complex visual, auditory, language, and sensory processing differences, difficulties with executive functioning, and specific learning disabilities before being assumed to have simple, uncomplicated ADHD. In addition, many children who spent their early lives in institutional care, lacking much direct human contact, have difficulties reading nonverbal social cues. As a result, they often have great difficulties with peer relationships and can benefit from direct teaching on social skills and reading body language.

Children who experience serious malnutrition, followed by significant catch-up growth, have a significantly higher risk for precocious puberty compared with the general population. In addition to a young age of onset, these children typically proceed through the stages of puberty at a very rapid rate, making early recognition and treatment imperative. Uncertainty about a child's true age can further complicate the evaluation.

Children who have experienced malnutrition also frequently have very weak dental enamel, which is often compounded by circumstances that lack even marginal oral hygiene. Many children experience severe dental decay despite good dental hygiene in the adoptive home. Early recognition and treatment of these conditions is obviously paramount.

Many adoptees have little or no knowledge of the biologic family medical history, and those who do often have only the information that was available at the time of their birth. This missing history can be a source of social and emotional distress to adolescents and their families, but for children of any age, it can also be a significant impediment to providing appropriate health care, particularly in the case of serious illness. Some states now provide registries of birth parent and adoptee information, with access granted by mutual consent. (See Tools for Practice for resources for adoption information.) Laws vary from state to state regarding who may have access to this

information and under what circumstances. Some adoption agencies also maintain and update health records of birth parents whose children they have placed, and some will help families locate birth parents. Children who were adopted from overseas generally have little or no information about birth family medical history, and records may or may not be maintained, thus precluding further investigation. Children who were abandoned have no way to know any family medical history. Lack of birth family medical history should be considered when determining risk factors for routine screening (eg, for hypercholesterolemia).

### **BILLING AND PAYMENT INFORMATION FOR ADOPTION PHYSICIAN SERVICES**

Preadoption consultation services are not billable to third-party payers because the child in question is not yet part of the policy. Pediatricians with a special interest in adoption medicine who perform these services frequently have fee-for-service fee scales that reflect the time spent, the complexity of information reviewed, and local prevailing payment rates. Pediatricians who perform these services only occasionally may choose to provide these services free of charge to families who are already in their practices, or they may devise a pay scale that reflects the same variables. Payment for these services may be available to some families by means of employer adoption subsidy plans or flexible spending accounts.

Office visits for newly adopted children require more time than standard well child visits, involve far more complex issues, and generally need to occur more frequently. Payment for these services can be accomplished by appropriately coding for the diagnoses involved and the complexity of medical decision making. When counseling or care coordination takes up more than 50% of the face-to-face time spent with a patient, the physician can use time as the controlling factor for assigning a procedure code.

### **ISSUES UNIQUE TO ADOPTIVE FAMILIES**

Adoptive families come in all shapes and sizes. These families may include children by birth and adoption, children and parents of different races, single parents, gay and lesbian parents, grandparents and other relatives raising children, and stepparents adopting a new spouse's children, just to name a few. Depending on the size and diversity of the community, some of these families may stick out, and parents and children will need to learn how to handle questions from strangers and acquaintances. Parents and pediatricians need to help children learn to interpret which questions are ill intended versus simply curious, what information is appropriate to share (with whom, when, and where), and what information is private. Children can and do thrive in all of these varieties of families, especially when parents are open and honest with children about these topics that are unique to adoptive families.

All pediatricians should be familiar with basic issues that are common to all adopted children and

should ensure that they and the entire office staff use language that reflects respect for adopted children and their birth and adoptive families. Box 70-2 provides appropriate language to use when speaking about adoption. Numerous resources are available to help parents, professionals, and children negotiate the complexities of grief, loss, and joy that come when a child is relinquished by one set of parents and claimed by another. (See Tools for Practice for these resources.)

Pediatricians should help and encourage adoptive parents to talk with their children about adoption from a very young age, given that all available research has shown that children do far better when they come to understand adoption over time, rather than as a single, bombshell discussion. Adoptive parents often struggle with how to begin these discussions and how to handle children's questions, fearing that they might jeopardize the child's sense of security or belonging in the family or that they might overwhelm the child with difficult-to-comprehend details. Just as with any other complicated matter, however, children come to understand the complexities of adoption over time and in more detail as they progress developmentally. Young children simply need to learn the language and can begin to understand that, "I didn't grow inside Mommy's tummy." Preschoolers ask many questions, and adoptive parents who respond openly to their inquiries are setting the stage for more in-depth, open dialogue as time goes on. School-aged children begin to understand that they have 2 sets of parents and spend a great deal of time thinking about their birth parents. They often fear talking about this subject with their adoptive parents, worrying that these questions will hurt the feelings of or minimize their love for their adoptive parents. Parents need to offer many opportunities for children to talk and clearly tell them that this topic of conversation is acceptable. Teens begin to incorporate what they know about their birth parents and their own stories into their developing identity and may experiment with lifestyles that they know or imagine their birth parents to be living. Anticipatory guidance for adopted children should include encouraging parents to talk openly and honestly in simple, direct, developmentally appropriate language to help the children understand and deal with the specific details of their own life's story.

Many adoptions, particularly domestic adoptions, include some degree of openness or ongoing contact between children and their birth parents. Although this idea is frightening at first to many prospective adoptive parents and might seem harmful to those unfamiliar with adoption, research and experience have shown that children thrive when birth and adoptive parents carefully and lovingly maintain relationships over time. Although these relationships can at times be complicated, the benefit to children of being able to know exactly why their birth parents chose not to raise them and of knowing details such as who they resemble, whose musical talent or crooked toes they inherited, and how their birth parents are doing today is beyond measure.

Children who do not have ongoing contact with their birth parents often, as they become adolescents

**BOX 70-2 Appropriate Language to Use When Speaking About Adoption**

The language we use to talk about adoption can have significant positive or negative effects on children and their families. Physicians and office staff members who speak respectfully and supportively about adoption not only nurture the self-esteem of their patients, but also win the respect of parents and receive word-of-mouth referrals of other adoptive families to the practice. Carefully worded office forms and publications provide further support for adoptive families.

The following list presents respectful ways to talk about adoption with families, as well as language and phrases to avoid.

- **DO:** Use the words “birth child” and “adopted child” **only** when they are relevant to the discussion (eg, in discussing family medical history); otherwise simply use “child.”
- **DON’T:** Refer to a child born to his parents as the parents’ “real child,” “own child,” or “natural child.” A child who was adopted is very real and not at all unnatural; she is very much her parents’ “own child.”
- **DO:** Use the words “birth parents” or “biologic parents” **only** when asking about them is relevant (eg, in discussing family medical history).
- **DON’T:** Refer to the child’s birth parents as his “real parents” or “natural parents.” Adoptive parents are very real and not at all unnatural.
- **DO:** Treat siblings who joined families by birth or adoption equally. They are loved equally by their parents and experience all of the joys and trials of any sibling relationship.
- **DON’T:** Distinguish between children who were adopted into the family and children who were born into the family unless it’s relevant.
- **DO:** Describe birth parents as choosing “to make an adoption plan for the child” or “to place the child for adoption.”
- **DON’T:** Refer to a child as being “put up” or “given up” for adoption. Most birth parents have thought long and hard about their decision to place a child for adoption. It is very important to a child’s self-esteem to know that her birth parents loved her and worked hard to reach a decision that they felt to be in her best interest. Even when birth parent rights are terminated involuntarily, the child needs to know that it wasn’t her fault that her birth parents could not take care of her at the time and that other adults are looking out for her best interests.
- **DO:** Recognize that families come in all shapes and sizes. Create forms, policies, and other office materials that refer to “parent or guardian” not “mother or father.” Some families may have a single adoptive parent or permanent legal guardian and no other legal parent. Other families have same-sex parents. Forms that ask for information from a parent or guardian acknowledge that families of all varieties are welcome.
- **DON’T:** Assume that the child has 2 opposite-sex parents.
- **DO:** Refer to birth parents as “choosing to parent” their child. This implies to the child who was adopted that birth parents made their decisions based on what they felt was in the best interest of each child when they made their decision.
- **DON’T:** Refer to birth parents as “choosing to keep” their child. This implies to a child who was adopted that he was “not worth keeping.”
- **DO:** Talk with a family about how it celebrates the intercultural and/or interracial nature of the family. Many families make special efforts to include their children’s culture and heritage in daily routines and traditions. Available research shows that children clearly benefit from this practice.
- **DON’T:** Ignore a child’s birth country, race, or genetic heritage. Especially in communities where there is limited ethnic diversity, children from racial or ethnic minorities need family and physician support to overcome racism and develop a strong, positive racial identity.
- **DO:** Recognize that a child understands adoption gradually as she grows, just as with all other developmental tasks. Ask the family whether it is dealing with any difficult adoption-related issues and be familiar with common issues of different developmental stages so that the family feels comfortable using office staff members as resources for information.
- **DON’T:** Ask, “Are you going to tell your son that he’s adopted?” Adoptive parents are encouraged to talk freely and honestly about adoption from the time their child is very young so that there is never a time in the child’s life when this information comes as shocking news.
- **DO:** Be sympathetic with the long and sometimes arduous path that parents have traveled to become parents. Some may be experiencing significant financial stresses after the adoption, some may still be grieving infertility losses, and some may be coping with extended family members who do not accept the new member of the family. Recognize that even though the child may not be a newborn, the adults may be new parents. Recognize that postadoption depression exists and is similar to postpartum depression.
- **DON’T:** Ask, “How much did you pay for your daughter?” Children are not bought. Fees go to pay social workers and attorneys, to complete court and government paperwork, to cover travel, medical, foster/orphanage care, and other expenses, not to “buy children.”

or adults, choose to search for them. Many adoption agencies and therapists offer help and support to adopted persons and their families as they proceed through this process. The emotional and legal complexities of this process vary from family to family and state to state, with some states allowing adoptees full access to records, some having mutual consent registries, and some allowing limited or no information to be obtained from sealed records. Pediatricians can help parents understand that the desire to search does not imply a rejection of the adoptive parents, but rather a need for the adopted person to fully understand himself. Some adoptees find and develop good relationships with their birth families, some find them but do not develop strong relationships, and others are never able to locate biologic relatives. Pediatricians need to support families as they negotiate all of these possibilities. (See Tools for Practice.)

Although most adoptive placements generate positive outcomes for both children and their families, not all adoptive placements achieve permanency for children or happy long-term outcomes. Although exact numbers are unclear because of variable state reporting systems, estimates indicate that between 10% and 25% of adoptive placements are disrupted (ended before the adoption is finalized), and 1% to 10% are dissolved (legally reversed, similar to a divorce, after the adoption was final). Most commonly, this event happens with children who are older, with a complicated, traumatic history and complex behavioral and mental health needs, who were placed with families who were either unaware of these needs or inadequately prepared to meet them. Such occurrences are traumatic for everyone involved, especially the child, and are best avoided by full disclosure of information before the adoption and long-term, ongoing support for the family after the adoption is finalized. Families who are considering or pursuing a disruption or dissolution of their adoption should be referred to an experienced adoption professional. (See Tools for Practice for parent resources about disruption and dissolution.) These same stresses, combined with unrealistic expectations, can also leave children at risk for abuse or neglect in their adoptive homes, just as can occur in any other family. Pediatricians should maintain the same surveillance for these possibilities as they would for any other child and family.

## CONCLUSION

Caring for adopted children and their families can be among the most rewarding experiences of a pediatrician's career. By working closely with parents to address the special needs of their adopted children, pediatricians can help ensure a bright future for children whose futures might otherwise have been bleak.

## Chapter 71

# CHILDREN OF DIVORCE

Rhonda Graves Acholonu, MD; Lori Legano, MD;  
Michael Weitzman, MD

Approximately 1 million children experience divorce in the United States each year. In the early 1960s, almost 90% of children spent their childhood and adolescence with 2 biological parents. Now, that number has decreased to 40%. For adults, divorce is second only to the death of a spouse or a parent in terms of its intensity as a stressor and the length of time required to adjust to it. Divorce often produces anger and a sense of failure for parents; conflicted loyalties, guilt, grief, and anxiety for children; and concern on the part of all about whether the children will suffer long-term harm. Most children of divorce experience, at the least, a potent transient stress. It should never be viewed, therefore, as an isolated event, but rather as a step in a series of family transitions that significantly affects both of the parents and the children. Many people accommodate to their new circumstances successfully, but a substantial percentage suffer long-term negative effects. Many of the problems of these children and their families can be anticipated, prevented, or alleviated by thoughtful and timely intervention.

## FAMILY CHANGES PRECIPITATED BY DIVORCE

In most cases, both parents are awarded joint legal custody, but the children's primary physical residence is with their mother in more than 80% of cases. Divorce often has devastating financial consequences for these children and their mothers, and children in postdivorce families are 4 times as likely to live in poverty compared with children overall. A significant number of divorced mothers have few financial and personal resources to direct toward the children, and many take on new employment arrangements. This circumstance may result in new child care arrangements for younger children, older children taking care of themselves or siblings for greater parts of the day, and curtailment of certain activities because of expense or parental time constraints.

For nonresidential parents, who are most often fathers, problems range from what to do with children on visiting days to profound concern about the emotional consequences for their children. Some nonresidential parents fear that their children will abandon them, some have unrealistic expectations about the kind of relationship they will have with their children, and some believe divorce deprives them of the right to exercise authority and to discipline the children. Much public attention has deservedly focused on issues of failed child support, nonresidential fathers who do not visit, and the economic plight

of single-parent households. The importance of long-term paternal involvement in a meaningful and unconflicted relationship with their children cannot be overstated.

## STAGES OF DIVORCE

The period immediately before and after the separation is referred to as the acute stage; it is characterized by maximal turmoil and generally lasts up to 2 years. The family then moves into the transitional stage, which is characterized by more controlled changes. The final stage is the postdivorce stage, when major family restructuring ceases.

During the acute stage, all family members are confronted with disruptions of their expectations, relationships, and support systems. Parents may be depressed, may be preoccupied with personal concerns, and may exhibit diminished parenting abilities. During this stage, 2 events appear to be most stressful to most children: learning about the divorce, and the actual departure of a parent. The first year after divorce is the year of maximal negative behavior by children and the poorest parenting by parents. The apparent intensity of a child's reaction to this stage, however, does not predict long-term adjustment. Initially, many parents make fewer demands on the children, communicate less effectively, are less affectionate, and have difficulty disciplining children. In a significant minority of divorces, the troubled relationship between parents continues indefinitely. In these cases, children have the greatest incidence of postdivorce maladjustment.

The transitional stage is marked by new undertakings for the single-parent household and more stability than the acute stage. Children must accommodate to their parents' new relationship with each other, to new friends, and often to new romantic partners of one or both parents. During this stage, children are often concerned about the well-being of, and their relationship with, the nonresidential parent. Visitation patterns tend to have become more stable, whether they are acceptable to all parties or not. The major exception to the general pattern of increased stability is the family in which the parents still are actively in conflict, either informally with each other and the children or formally through the legal system.

In the postdivorce stage, relative stability is achieved. The family may still be headed by one parent, or a stepparent may now be present. Remarriage does not convey automatic stability but rather requires new adjustments as a result of the reawakening of unresolved issues and new roles in the new family.

## EFFECTS OF DIVORCE ON CHILDREN

On average, small but detectable negative emotional, cognitive, social, and physical effects, both short term and long term, are found among children of divorce. Of course, these effects vary greatly and depend on many factors.

### Initial Effects

Initial responses are greatly influenced by the developmental level of the child; the child's temperament; the level of parental conflict; and the emotional,

cognitive, and economic support available to the child. The effects of divorce on children are similar for male and female family members.

Infants and toddlers have minimal to no comprehension that divorce has occurred and may not have a direct reaction to the divorce. Preschoolers, aged 2 to 5 years, initially tend to display regressive behaviors that can be highly stressful for parents, such as sleep disturbances, temper tantrums, separation anxiety, loss of bowel and bladder control, and increased need for parental attention. School-aged children, 5½ to 12 years of age, may experience sadness, grief, or intense anger at one or both parents. School performance and peer relationships may deteriorate, and phobias may emerge among both early and late school-aged children. Adolescents of divorcing parents find themselves without the expected home base from which to move away. This situation may result in insecurity, loneliness, decreased self-esteem, and depression. These feelings may be overtly or covertly expressed in diminished school performance, school failure, truancy, violent and nonviolent criminal behavior, substance use, eating disorders, or sexual promiscuity. Children of any age may exhibit psychosomatic symptoms as a reaction to the stressors placed on them by the divorce. These children may play one parent against the other to gain more control.

### Long-Term Effects

Prior studies revealed long-lasting effects of parental divorce in a significant minority of cases. Adults who experienced divorce as children tend to score lower on a variety of indicators of psychological, interpersonal, and socioeconomic well-being. Although the majority of adults who experienced divorce as children appear to do well, as a group overall, they have higher rates of depression, job changes, premarital pregnancies, and divorce. The degree of marital conflict before the divorce has been shown to be a stronger predictor of adjustment than the divorce itself or the conflicts after the divorce.

A 25-year follow-up study confirmed that children of divorced parents are less likely to marry and when they do marry are more likely to divorce. They are also less likely to enter and complete college. The gap between children of divorced and married parents with respect to academic achievement, psychological well-being, self-concept, and social relations was small in both the 1980s and 1990s, although a trend for a wider gap occurred in the 1990s. The differences in outcomes between children of married and divorced parents may be influenced by ethnicity, with smaller differences seen in black families than in European American families. The long-term negative effects of divorce are mitigated by a variety of social factors: support of parents and grandparents, social support in adulthood, educational attainment by the child and mother, and socioeconomic status of the family.

Not all effects of divorce are negative, however. Children from divorced families demonstrate less stereotyped sexual behavior, greater maturity, and greater independence.

## TASKS FOR THE CHILDREN AND PARENTS OF DIVORCE

Children of divorce have several specific tasks on which they work simultaneously and with varying degrees of success. These tasks greatly depend on the child's development and age. Mastery of these tasks is facilitated by support and cooperation of both parents. Parents can better help children cope with divorce if they are aware of the child's developmental age and respond to them accordingly.

### Understanding the Meaning of Divorce and Custody

Toddlers and preschoolers may have a difficult time understanding the meaning of divorce. Because these children view their world very concretely, they may not be able to comprehend the changes in relationships and the alterations within their household. Confusion about the actual meaning of divorce is the rule rather than the exception. Parents should provide simple explanations about the meaning of divorce and custody and should never avoid the subject. Parents should maintain routines so that the child does not equate divorce with instability or loss of normalcy.

### Accepting the Permanency of Divorce

The task of acceptance requires the child to accept the reality of the divorce despite tendencies to deny the dissolution of the family and fears of abandonment. These tendencies and fears may persist, leading to repeated efforts by children to persuade their parents to reconcile, even after one or more has remarried. Young school-aged children fantasize about being able to reunite their parents. Parents need to recognize that their children have these fantasies and that they will try to get them to interact with each other in any way and as often as possible. Older children and adolescents who have lived in persistent high-conflict or violent marriages, however, are more likely to be relieved about parental separation and are less likely to wish for parental reunion.

### Regaining a Sense of Direction

Immediately after divorce, many children experience emotional and behavioral difficulties, and many seem to lose interest in school, friends, and leisure time activities. Approximately one-third of adolescents, particularly boys, in divorced and remarried families separate from the family unit, spend little time at home, and avoid interactions with family members. Generally, the return to more typical activities for the child takes approximately 1 year. If this transition has not occurred within this period, then referral of the child or family for psychotherapy may be indicated. During this time, parents must maintain discipline and avoid allowing their own emotions surrounding the divorce to cloud their judgment and authority. If a child is having a particularly difficult time adjusting in one home, parents may then consider a trial of living with the noncustodial parent. Children who are better adjusted before the marital breakup, those who are not enmeshed in a prolonged battle between the parents, and those who are supported in their efforts to

understand their feelings are better able to accomplish this task.

### Dealing With Painful Feelings

Departure of a parent through divorce is experienced by children of all ages as a major assault on their self-esteem and sense of security. Because of preschoolers' egocentric thinking, they may believe that they are responsible for the divorce, must therefore be bad, and consequently are at risk for further abandonment by the other parent. Older children, appreciating that the departing parent is exercising a choice to leave, often feel anger as well as other negative aspects of grief. These feelings result in a complex interplay of negative emotions and their consequences. Parents should explain the situation to their children in simple, age-appropriate language and assure them that they are not the cause of the divorce. Despite parents' best efforts, however, long-term follow-up studies indicate that this important task may never be accomplished by a significant number of individuals who experienced divorce as children.

### Not Choosing Sides

Children, especially school-aged children, may see divorce as posing a problem of conflicting loyalties. Parents must consistently reassure children that they are equally loved by both of them and that divorce is not going to change these feelings. Parents should also refrain from buying excessive gifts to prove their affection.

### Remaining a Child

Divorce leads to many changes, but one of the most obvious is the physical absence of one parent in the home. Older adolescents often feel responsible for the happiness of their parents and the well-being of their younger siblings. They may make attempts to comfort and console their parents. Parents should avoid treating their children as adults. Boys should not be expected to become the men of the house, and girls should not be expected to become the cooks. Children's lives will undergo enough changes without also relinquishing their childhood.

### Forgiving the Parents

Forgiving the parents is often a task for older children. Adolescents often struggle with chaos in their own lives and are often angered by having to deal with their parents' lives. Forgiving their parents therefore requires their ability to appreciate the parents' need to separate as being more important than any reason to stay together, including the desires of the children. Children must then overcome grief over the loss of the intact family as well as the anger and resentment generated by the resulting changes in their life. Parents should be flexible and understanding of the adolescent's need for space as well as available for comfort and maintenance of discipline.

### Resolving Issues of Relationship

As Judith Wallerstein has observed, divorce often leaves children fearful and unable "to reach, sustain, and support the personal vision that love, mutual

understanding, and constancy are expectable components of human relationships. Perhaps the major developmental task posed by divorce is this: to achieve realistic hope regarding future relationships and the enduring ability to love and be loved." "At young adulthood, when love, sexual intimacy, commitment and marriage take center stage, children of divorce are haunted by the ghosts of their parents' divorce and are frightened that the same fate awaits them." This task is difficult for a significant number of adults who experienced divorce as children. As children get older, parents should discuss the reasons for the divorce so that the young person learns to view the divorce "not as inevitable but as a result of avoidable human error."

### CUSTODY

If the noncustodial or nonresidential parent has not abandoned the family and wants to remain involved with the children, then the custodial or residential parent must not attempt to sabotage this relationship.

### REMARRIAGE AND STEPFAMILIES

Within 4 years, 50% of divorced adults remarry, and one-third of American children will eventually become members of a stepfamily. More than 80% of these stepfamilies are composed of a biological mother and a stepfather. In many cases, it restores a secure, 2-parent environment, and it may provide children with a model of a loving, caring adult relationship. Despite the wicked stepmother figure portrayed in fairy tales, most stepchildren like their stepparents and report that they get along with them well. Most studies have shown that stepchildren do not appear to differ from other children in personality characteristics or in cognitive or intellectual accomplishments.

Remarriage does, however, have the potential of creating new tensions and stresses for both the parent and the child. When one parent remarries, the other may fear that the children will abandon them for the new stepparent. Lutz's interviews of adolescents between 12 and 18 years of age living in stepfamilies revealed that the areas causing the most difficulty are those of divided loyalty and discipline. Many children may feel conflicted about loving their stepparent and may even see it as a source of betrayal of their biological parent. In addition, many children may continue to wish for parental reunion. Regarding discipline, stepparents are often unsure of their roles and may feel awkward in these situations. Discussing these issues with the custodial biological parent and conforming to their approaches is important for stepparents.

Adults can help children adapt better to remarriage. Children adjust better to remarriage with decreased conflict among family members and a supportive residential parent and stepparent. The stepparent should not exert authority immediately but instead be supportive of the residential parent. Social support from peers, grandparents, and school personnel may positively influence the child's adjustment.

Two other factors may play significant roles in the adjustment of children within stepfamilies. First, the child's age is an important aspect to consider in the evaluation. Although a toddler may not fully

understand the implications of a stepparent, the school-aged child has been found to be the most vulnerable to the stresses associated with the remarriage. Second, timing is equally important to the overall adjustment. If the remarriage occurs abruptly or before the child is ready to accept a new parent in the child's life, the stress may be magnified. Unfortunately, the divorce rate of second marriages is still higher than that of first marriages.

### PREVENTIVE INTERVENTIONS FOR DIVORCING FAMILIES

Different interventions have been attempted to help alleviate the deleterious effects of divorce on families. Court-connected divorce education programs have been developed to inform parents how children respond to divorce and to help parents respond to the child's needs. Evaluations of these programs are sparse. Mediation of divorce and custody issues promotes higher levels of agreement among parents before the court hearing than the adversarial process. Therapy for the mother and child can reduce symptoms of mental disorders; reduce marijuana, alcohol, and other drug use; and reduce sexual promiscuity. An intervention to improve the quality of the mother-child relationship was shown to improve long-term coping in children.

### THE PEDIATRICIAN'S ROLE

The pediatrician can help the family anticipate, prevent, or address problems that frequently accompany divorce by providing anticipatory guidance and counseling for problems as they arise, and assessing and referring children and family members for more extensive or detailed psychosocial intervention when needed. Parents and courts also may ask that pediatricians offer expert witness testimony when custody is questioned.

The first year after divorce is often the worst; parents often feel depressed and angry. If the parents are not otherwise receiving counseling, then the pediatrician may offer to meet with one or preferably both of them to facilitate cooperation regarding child-related issues, such as helping the parents formulate an approach to informing the children about the divorce. Pediatricians need to be the advocate for the child. They should avoid taking sides between parents, and they should be aware that one parent may manipulate the other by using the pediatrician.

Parents should be encouraged to avoid placing the children in the difficult position of choosing which parent to believe or side with when the 2 most significant adults in their lives have widely differing views. They should also be informed that behind many of their questions, children are asking, "Do you still love me, and can I trust you?" Parents should explain the divorce process to children in a developmentally appropriate manner. Also suggested is that parents be *concrete* about the children's future: where they will live, who will care for them, where the nonresidential parent will live, and how often he or she will visit. Parents should be encouraged to maintain children's routines, including going to school and taking on

responsibilities in and outside the home. Parents should maintain consistent discipline strategies.

Both before and after the divorce, children need reassurance that they are not unique as offspring of divorced parents. They may find comfort in discovering that many other children have divorced parents, live in stepfamilies, and have the feelings they are having, and that nothing is wrong with feeling this way. They should also be encouraged to ask questions and express feelings, and they should be brought to realize that expending a great amount of energy hoping their parents will be reunited is useless. Visitation with the nonresidential parent may be court mediated. Pediatricians need to be aware of the visitation agreement that is permitted; the pediatrician can then offer guidance about how to make visits more comfortable for the child. Suggestions that can be given to make this visitation easier include allowing the child to bring a friend along so that the child will not be bored, setting up the child's room as it was in the original home, spending time with the child, and not expecting the child to fit into the noncustodial parent's new world.

If a child does not wish to visit, then parents should be informed that the child should not be made to feel guilty, and the offer to visit soon should be extended. The nonresidential parent should be counseled to avoid forcing visitation if the child refuses. Persistent refusals to visit the nonresidential parent may suggest that the child is enmeshed in parental difficulties or is siding with the residential parent, or that the residential parent may be using the child to hurt the nonresidential parent.

Pediatricians should work with both parents; if abuse by a parent is thought to exist, however, then the appropriate action should be taken. Pediatricians should be knowledgeable about confidentiality laws; sharing medical information with any party during a divorce proceeding requires written permission by both parents or a court order. Pediatricians should maintain an accurate record of the custody arrangements.

Visits for well-child care and for acute illnesses can be used routinely to assess children's adjustment and to determine the need for further counseling by the primary care physician or for referral for individual or family therapy.

## Chapter 72

## CHILDREN IN FOSTER OR KINSHIP CARE

Maira Szilagyi, MD, PhD; Sandra H. Jee, MD, MPH

In an ideal world, every child would be reared by nurturing and caring birth parents. Many children and adolescents, however, cannot reside with their birth families for reasons of health and safety, and they require care in other settings. In 2013, approximately 3.5 million reports alleging child abuse and neglect and involving 6.4 million children were investigated by child protective services, resulting in 679,000 children identified as victims. About 144,000 child victims were removed to out of home care, as were another 95,000 nonvictims, mostly adolescents. In most states, kinship care remains a less formal arrangement and includes care by extended family, neighbors, or friends, frequently without the oversight of child welfare services. Foster and kinship care are intended to be a temporary respite for a family in crisis, and there is an increasing trend toward keeping children with their parents or extended family in lieu of foster care.

Although adolescents in out-of-home care frequently enter because of parental inability to cope with their behavioral or emotional issues, they have often experienced abuse and neglect during their childhoods. When children or adolescents are removed from their family of origin by child welfare services, they may be placed in either foster family care, kinship care, or group care. Although this chapter focuses on children and adolescents in out-of-home care, the information applies to the larger population of children and teens whose families are involved with child welfare because they experience similar childhood adversities and trauma as children in foster and kinship care.

In the United States, on September 30, 2014, approximately 402,378 children and adolescents resided in foster care, with approximately 28% in care with extended family members. Furthermore, estimates suggest that more than 600,000 individual children resided in foster care during the preceding 12 months and that approximately 4 times as many children and teens live in informal, unregulated kinship care. These children are, by and large, the children of the indigent, and 70% have a documented history of child abuse or neglect. However, children enter foster or kinship care after experiencing many other severe childhood adversities and trauma that can result in toxic stress and negatively affect health and well-being. More than 80% have been exposed to high levels of violence in their homes or communities, with more than 40% living in homes with active domestic violence at the time of removal. Close to one-half (48%) have a caregiver with a significant mental health impairment, and rates of parental substance and alcohol abuse are enormous, ranging up to 80% for the youngest children. These children have often had multiple caregivers even before removal and have not experienced the predictable, responsive parenting that promotes well-being. Despite such high levels of family dysfunction, removal from their family of origin and all that is familiar is emotionally traumatic for almost all children. Placement in foster or kinship care is intended to nurture and heal children while facilitating the rehabilitation of their families. In reality, foster care has become a system of last resort for the most vulnerable children and challenging families.

Most pediatric practitioners will encounter children and adolescents in foster or kinship care, or otherwise involved with child welfare, during the course of their practice; thus, it is important to be familiar with the effects of and treatment for child abuse and neglect, as well as the effects of early childhood trauma, removal, and placement in foster or kinship care on children, adolescents, and their families.

## SUMMARY OF KEY LEGISLATION

The foster care system seems always to be in a state of flux, burdened by huge caseloads, birth families with multiple intractable problems, inadequate funding, and complex and often conflicting bureaucratic, legal, and ethical demands. The recognition that separating children from their families only to leave them lingering in foster care without permanency was harmful to children, together with burgeoning costs, led to several attempts at reforming child welfare. In 1980 the Adoption

Assistance and Child Welfare Act (PL 96–272) mandated states to provide preventive services (eg, counseling, child care, parenting education, drug rehabilitation) to avert the removal of children from their birth families. Agencies were also mandated to conduct semiannual case reviews and to develop permanency plans within 18 months of placement. In an effort to move children out of the system, adoption subsidies were funded so that a marginal family income would be less of a hindrance to the adoption of children out of foster care. After enactment of PL 96–272 the size of the foster care population transiently declined until the cocaine epidemic led to a dramatic increase in the number of very young children in foster care in the late 1980s and early 1990s.

More recent federal legislation, rooted in emerging research and knowledge about the effect of foster care, childhood trauma, and lack of permanency, now largely defines the goals and operations of foster care. First, the Adoption and Safe Families Act (ASFA) of 1997 (PL 105–89) shifted the emphasis in child welfare toward the health and safety of the child and timely permanency planning. States are now obligated to pursue termination of parental rights for any child who has been in foster care for 15 of the prior 22 months, unless there is a compelling reason not to, such as impending reunification. Under ASFA, adoption subsidies were further enhanced, leading to a surge in adoptions in many states in the late 1990s and the early years of this century. The shorter timelines for permanency and termination of parental rights competed with the goal to reunify children with their families and led to the concept of *concurrent planning* for reunification and alternative permanency arrangements, now the hallmark of foster care work.

The second piece of legislation, the Chafee Foster Care Independence Act of 1999, allowed states the option of extending certain benefits, such as Medicaid, to youth aging out of foster care until they turned 21 years of age. Although many states took advantage of this option to enhance resources for adolescents in their independent living programs, it had less effect than other legislation because it was largely optional and inadequately funded.

During the period between 1995 and 2007, several studies reported that children and adolescents achieve more stable placement in kinship care and kin caregivers report fewer behavioral problems. This resulted in an increased emphasis on assessing and using extended family and *kin* as potential placement resources and a dramatic increase (300%) in kinship care placements during the period between 1995 and 2005. Two major pieces of child welfare legislation, the Fostering Connections to Success and Increasing Adoptions Act of 2008 (PL 110–351) ([www.fosteringconnections.org](http://www.fosteringconnections.org)), and the CAPTA Reauthorization Act of 2010 (PL 111–320) addressed the issues of kinship care, independent living, education, tribal foster care, and adoption supports for children in foster care. Foster care agencies must identify kinship resources at entry to foster care, promote and support kinship care, maintain children in their schools of origin, and support Native American tribes in keeping children within their own foster care systems. Resources for youth with a goal of independent living were also increased.

Of particular relevance to pediatric professionals, the Fostering Connections Act, the Child and Family Services Improvement and Innovation Act (PL 112–34) and the Patient Protection and Affordable Care Act (ACA) (PL 111–148) specifically address health care services and resources for children in foster care. Together, these federal laws require states to develop health oversight systems for children in foster care, monitor and treat emotional trauma, coordinate health care, monitor psychotropic medication use, connect children with medical homes, and measure outcomes. The ACA, in particular, grants those who emancipate from foster care at age 18 years or older automatic Medicaid eligibility until age 26 years.

### TRENDS IN OUT-OF-HOME CARE

Legislative and policy changes and scientific studies ultimately affect foster care practice. With the emphasis on kinship care, increasing numbers of children are entering foster care for very short stays while the child welfare agency attempts to identify and investigate kinship resources. The definition of kin has expanded to include nonrelatives with some familiarity with the child or family. Children residing in kinship homes achieve permanency in these placements at a higher rate than those in foster care, although an unknown percentage of kinship homes disrupt, leading to subsequent foster or other kin care placement.

Adoptions out of foster care peaked in the early part of the millennium. The children who remain in care awaiting adoption are older, minority, part of large sibling groups, or disabled. In some locales, parental methamphetamine abuse has become an increasingly important reason for removing children. The system has become more focused on the effect of childhood trauma and evidence-based interventions to treat children and families, although resources are often scarce. Foster parents remain the major therapeutic intervention of the foster care system, and there are some elegant studies about specific education and supports for foster parents and birth parents that improve outcomes for children, although they have yet to be adopted widely. A recent study that looked at child welfare trends over the past decade demonstrated that child maltreatment referrals have increased but foster care admissions have decreased. During this time frame, the complexity of children in foster care has increased as measured by the larger number of children with multiple forms of maltreatment and diagnosed as emotionally disturbed.

### RISK FACTORS FOR PLACEMENT

Families whose children reside in foster care are, in general, impoverished and living on the fringes of society, with few social supports. Child neglect, including neglect of basic nutritional needs, educational and medical neglect, and lack of supervision, is the most commonly cited reason for placement. Reports of child physical abuse and sexual abuse have declined in the past decade but, along with abandonment, remain reasons for placement. More children, however, reportedly experience multiple forms of maltreatment, although it is unclear whether this reflects a true increase or improved reporting. Although child abuse

and neglect occur in all sociodemographic groups, young people placed in foster care come from the most economically deprived segments of society; thus, extreme poverty remains the pervasive common factor underlying foster care placement. Parental mental illness, substance abuse, active domestic violence, and criminal activity permeate the environments in which children have lived before removal. More than 80% of young children entering foster care have a parent who abuses drugs, alcohol, or both. Many children come from homes and neighborhoods in which drug sales and the presence of drug paraphernalia are common. National data indicate that 48% of parents have a mental illness and 10% are cognitively impaired. Before foster care, 44% of children were living in homes with active domestic violence, and 84% experienced significant levels of violence in their homes, schools, or neighborhoods. In one national dataset, child protective services caseworkers identified 80% of birth parents as having significantly impaired parenting skills at the time of the child protective services investigation. Other social stressors in these families include single parenthood, lack of education, and unemployment. Approximately one-third of birth parents admit to being abused or neglected as children, and approximately the same number spent time in foster care. Removal of a child often occurs after prolonged involvement with social service agencies, including child protective services, when preventive strategies have been exhausted and the child's health and safety are at imminent risk.

Early childhood trauma or multiple adverse childhood experiences and chronic stress have been shown in multiple studies to be associated with very poor long-term mental health, developmental, and physical health outcomes. Trauma and chronic stress, especially in the absence of protective factors, alter the neurobiology of the brain, especially in the young child, affecting those areas involved in cognition, rational thought, emotional regulation, activity level, and the relationship between thought and emotion. (See Chapter 68, Children Exposed to Adverse Childhood Experiences.) Thus, children entering foster care, with their cumulative and often chronic adverse experiences and early life traumas, are a group with immense emotional, developmental, and physical health needs. Studies on resiliency and recovery from traumatic experiences are just now accumulating, but early data indicate that children need stability in nurturing and responsive families and communities for healing after such experiences.

### FOSTER CARE SYSTEM

The foster care system, simple in its conception of providing needy children with nurturing families, is in fact a complex bureaucracy. Federal legislation determines patterns of funding and regulatory guidelines, but responsibility for the structure and implementation of foster care programs resides with state social service agencies, which may delegate daily management to county or private child welfare agencies.

#### Role of Caseworkers

Each child welfare agency retains the responsibility for hiring caseworkers and training foster families.

There are 2 foster care systems, public and private. In the public system, children are placed in care of the public agency that hires and trains both caseworkers and foster parents. The private system in each state consists of individual foster care agencies that hire and train their own caseworkers and foster parents. The public system has administrative oversight of the private system. In recent years, there has been a move toward privatization, despite occasional reports of poor training and oversight of such agencies. Child welfare casework is a demanding job requiring multiple skills. Although the professional demands of casework are more commensurate with master's-level social work skills, casework positions are entry-level jobs in most child welfare agencies, requiring no more than 2 years of college education. As advocates for the biologic family, caseworkers must engage the parent around the care of their child while undertaking a *diligent effort* to rehabilitate the parent or parents, ensuring the accessibility of whatever educational or service resources are necessary (eg, housing, counseling, medical care, drug and alcohol rehabilitation) for reunification. Meanwhile, they must also coordinate educational, developmental, medical, and mental health services for children and teens in their care. When birth parents are noncompliant or unable to undertake the work necessary for reunification, caseworkers have the delicate task of supporting them through the process of developing an alternate permanency plan and enabling the child to develop secure attachments and a sense of belonging in a different family than the family of origin. Caseworkers also recruit, train, monitor, annually recertify, and investigate minor complaints about foster homes.

Caseworkers must have a working familiarity with the legal system in their state, particularly the family court and juvenile justice systems. Within 72 hours of removal of the child from the home, the foster care agency's attorney working with the caseworker must prepare a petition for the court documenting the reasons for removal. Many children are returned to the birth parents within this time frame if the court finds insufficient basis for the removal. When the child or adolescent remains in foster care the caseworker must return to court at intervals to provide ongoing documentation for the continuation of placement and to detail their own efforts at rehabilitation of parents, reunification, and alternate permanency planning. Children may have multiple caseworkers while in foster care. Initially, they have an investigative caseworker, but they are transitioned to a foster care caseworker in approximately 90 days. This caseworker is also assigned to the birth parents. Caseworker turnover is high in most systems, so even when a child stays on a specific foster care team, he or she may transition through several caseworkers. If a child is freed for adoption, the case moves to an adoption team. A youth preparing for emancipation may transition to an independent living team. Each team transition involves a change in caseworker. Multiple transitions add to the losses children experience and can be frustrating in terms of case continuity.

### Other Child Advocates

Representation of children in foster care in court varies by state. Currently, about 30 states require the appointment of attorneys for abused and neglected children. In other states, the dependency court may appoint a guardian ad litem who may or may not be an attorney. The court may also designate a court-appointed special advocate (CASA) on behalf of the child in particularly difficult cases, although CASAs are not available in every state or community. As trained volunteers who are not attorneys, CASAs devote many hours to investigating the child's circumstances for presentation to the court. In some states, CASAs are the nonattorney guardians ad litem. Youth in foster care who are also involved with the juvenile justice system may lose legal representation after their probation ends, but hearings in dependency court will continue, with or without legal representation for the youth, on a prescribed schedule as long as the youth is in foster care. Pediatricians caring for children in foster care may wish to develop an understanding of the laws governing child representation in dependency court in their state, or at least determine whether their patients who are in foster care have representation.

### Termination of Parental Rights

Legally, parents retain guardianship of their children who are residing in the *care and custody* of the state or county commissioner of social services. Guardianship can only be terminated as part of a legal process, in which the commissioner then becomes the child's legal guardian until the child either reaches the age of majority or is adopted. Parents sometimes choose to surrender their children for adoption, but more often, termination of parental rights (TPR) occurs involuntarily after all efforts at reunification have failed. The TPR process can take years, during which time concurrent, but conflicting, efforts at reunification and alternative permanency planning occur. The time constraints imposed by ASFA legislation on beginning the TPR process and the increased focus on children's health and safety were intended to shorten the time between placement and TPR (and thus adoption) for children for whom reunification is not an option.

### CHILDREN IN FOSTER CARE

Entry into foster care is fraught with uncertainty, upheaval, and losses for children and for parents. The family, no matter how dysfunctional, is the center of the child's world. The child or adolescent is removed from family and all that is familiar. Except for the youngest infants, removal is an emotionally traumatizing experience for almost all children. Nonetheless, it is required for the child's health and safety, and in fact it is only after removal that some children and teens feel safe for the very first time.

Child protective services are now required by federal law to identify kinship resources before placement in nonrelative foster care. However, in emergent removals, agencies may first place children in a shelter or an emergency foster home pending the availability of a traditional foster home. Most foster parents are kind and welcoming but unfamiliar to the child.

Placement with kin caregivers can be less traumatic if the child already has a meaningful relationship with them. Within the first few days the child meets a variety of strangers, from child protective service personnel and foster care caseworkers to police officers, health care providers, and members of the foster home. Little privacy is afforded, and most children, grieving the loss of their home and families, are uncertain when they will see them again, are afraid to ask questions, and feel alone and isolated. Most child welfare professionals view this period as one of traumatic grief for the overwhelmed and confused child. Some children will externalize that grief, while others internalize it and seem compliant and passive. As children and teens adjust to their new circumstances, some will act out their anger, frustration, and sadness. Children with severe trauma histories may have developed certain behaviors that were adaptive in their previous environments but are highly maladaptive in their new environments. Most children are simply overwhelmed by feelings they do not understand and cannot express in healthier ways or control. Pediatric professionals can help caregivers understand children's behaviors and grief responses in terms of their trauma experiences. The American Academy of Pediatrics (AAP) has produced a guidebook on *Helping Foster and Adoptive Families Cope With Trauma*.

Children removed from their families spend varying lengths of time in foster care. Although many children (approximately 50%) cycle through foster care in weeks to months, approximately 10% to 20% remain in the system for years—as their families repeatedly fail to meet the goals set for reunification—and resist other permanency options. In 2014, 48% of children were in care for fewer than 12 months, but this may not have included, in some states, those who spent a few days in care but never reached the status of court adjudication. The mean length of stay in foster care was 22 months, whereas the median was 13 months. In 2014, 17% of children had been in foster care for more than 3 years and 8% for more than 5 years. The largest determinant of length of stay is the biologic family's level of cooperation with the individualized case plan for their child or children, although reports indicate that minorities, older children, and children with severe behavioral and developmental disabilities are almost twice as likely to remain in care. The average length of stay in the foster care system has declined from its high of just more than 5 years to approximately 2.5 years, attributed in part to increased efforts at reunification, greater dependence on relatives as resources, and more intensive permanency planning.

Longer stays in foster care are associated with a reduced likelihood of reunification and an increased number of placements. Changes in foster care placement are almost always traumatic for children, given that each transition involves a loss that reinforces feelings of rejection and worthlessness. Approximately 50% of children and teens in foster care will experience more than 1 placement, with approximately 25% having 3 or more placements. Reasons for disrupted placements vary; however, most frequently, a child's behavior problems are beyond the skills of a particular foster parent or deteriorate to the point at which the

child needs a higher level of care. Stable foster or kinship care is associated with improved outcomes. Less often, placements disrupt because foster parents retire, become ill or die, feel threatened by the birth parent, or move out of the child's community. Some placement changes occur in order to reunify siblings. Approximately 20% of all foster homes close each year, and about half of this number are closed by child welfare agencies for inadequate care.

Although the genders are fairly equally represented in foster care, the preponderance of children of black and mixed racial heritage in out-of-home care is high, reflecting, in part, their numbers in the poorer segments of society. As foster care numbers have declined 25% over the last decade, the numbers of African-American children have declined even more (about 40%) as child welfare has focused on reducing bias in investigation and removal. However, concern exists that the overrepresentation of minority children in foster care reflects overselection in investigation and removal. In 2014, 24% were black/non-Hispanic, 20% were Hispanic, 6% were multiracial or of other races, and 45% were white. The average age of a child in foster care in 2014 was 7.5 years. Although 53% of children live in nonrelative foster care and 13% reside in preadoptive homes, 24% reside in kinship homes and 8% live in group home or residential care. Unaccompanied refugee minors, especially from Central America, Africa, and Haiti, represent a very small proportion of the total foster care population.

Uncertainty, powerlessness, and guilt pervade the life of the child in foster care. Children in foster care often deny awareness of the reason for placement, and younger children may blame themselves for the disruption of their families. Children do not know how long they will be in care, whether their parent will arrive for visits, or when their parent will get out of jail or rehabilitation. Most children worry about the well-being of their parents and siblings. Birth parents may make promises they do not or cannot keep. Children are sometimes discharged from foster care or transitioned between placements without preparation. Other children tease them about being in foster care, contributing to their already poor self-regard and sense of alienation. Younger children and infants quickly form attachments to foster parents and may view their less frequently seen birth parent as a stranger. Differences in parenting style, as well as outright conflict between birth parents and current caregivers, creates confusion for children and teens.

## ADOLESCENTS IN FOSTER CARE

Adolescents in foster care are a varied group; most enter foster care through juvenile detention or Persons in Need of Supervision (PINS) petitions. Those placed through PINS petitions are placed because they have failed to attend school or have repeatedly run away from home or defied curfew or otherwise placed themselves at risk. Occasionally, teens are placed when a parent is unable to afford appropriate mental health care. Some adolescents have grown up in foster care, and this group is likely to have experienced a variety of foster care settings over time. Some members of this group are intellectually disabled or developmentally

delayed, with significant behavior issues. They may have lingered in care because a suitable adoptive home was never identified. Pregnant or parenting teens are a small group who may be living with their children in foster care or placed separately if they have significant mental health issues or constitute a risk to their offspring. A small group enters foster care as emancipated refugee minors, having immigrated to the United States from a variety of war-torn countries after surviving war, rape, injury, or the death of their families. Most emancipated refugee minor teens are now arriving from various regions of Central America.

Most adolescents in foster care reside in group homes or residential treatment facilities where their activities are restricted, their education is structured, and they receive mental health services and substance abuse treatment, if needed. The outcomes of residential and group home care have not been adequately studied, and little is known about the prevalence of evidence-based treatment in such settings. A minority of teens in foster care reside in foster families. In general, adolescents in foster care have had adverse life experiences similar to those of younger children entering foster care but have also experienced many transitions and engaged in high-risk behaviors, including substance abuse, sexual activity, school truancy, and petty criminal mischief.

Adolescents in foster care are less likely to be adopted than younger children. When they do leave foster care, they do so to return home or because they *age out* at age 18 years (an increasing number of states allow teens who are in school or job training to remain in foster care until age 21 years), run away, or are moved to another agency or placement setting (residential care or group home care, jail, or inpatient mental health or drug and alcohol treatment). Foster care caseworkers are charged with preparing adolescents who are aging out of care for independent living by offering them education regarding finances, job training, and health insurance. However, resources for independent living education are limited, transitional services are few, and youth aging out of care often find their way back to their family of origin if they have no sense of belonging elsewhere. Foster or kin families who remain invested in youth are their best resource, and youth who identify and remain connected to adult mentors seem to fare better. A recent study showed that about half of teens can form a stable attachment relationship to a long-term foster caregiver despite ongoing unstable attachment to their birth parent.

Little is known about the outcomes of youth who have aged out, and what is known is discouraging. There are no studies that look at the spectrum of young adults who once lived in foster care. In the few prevalence studies available, young adults who are a decade removed from foster care are underemployed and undereducated, have difficulty with trust in intimate relationships, and blame the child welfare system for the disruption of their families. In prevalence studies, adults with a history of foster care are over-represented among the homeless and the incarcerated. It is not known, in general, whether young adults who were adopted fare better than those who remained in foster care or reunified or lived with kinship caregivers.

Adolescence is the time during which the individual is supposed to form a stable identity rooted in self-esteem, a sense of autonomy rooted in self-efficacy, and a larger sense of commitment and comfort in relatedness to peers. For young people in foster care, especially minority youth, negative self-concept, lack of self-esteem, and a lack of self-efficacy are likely outcomes because of early adverse experiences, the accrual of multiple losses over time, and a sense of helpless dependence developed from living in the uncertain world of foster care. Early abuse and neglect coupled with impaired caregiving, repeated separation and losses, unpredictability, and a lack of role models for healthy relationships result in a high prevalence of young adults who are isolated, alienated, dependent, and prone to distrust.

## VISITATION

For the child who remains in foster care, even in a stable placement, major issues must be addressed. Although consistent visitation with the biologic family is the best predictor of reunification, visits are laden with difficulty for the child. The tenor of the parent-child relationship is variable. Children who have been abused or severely neglected by their parents may not feel safe even in a supervised visitation setting. Birth parents may attempt to sabotage the relationship of the child with his or her current caregivers, and vice versa. Parents may visit inconsistently, which is confusing and frightening for children. When the parent does come, the visit ends with the child reliving the initial separation from his or her parent. When the parent fails to show, feelings of rejection and abandonment are reinforced.

Visitation usually progresses through stages, beginning with visits supervised by caseworkers in a neutral setting. Visits then transition to the parent's home, where they may be monitored before eventually becoming unsupervised. Kinship placement may allow for more frequent contact with the birth parent, but kin caregivers may also be in a particularly difficult situation regarding visitation if they harbor resentment toward the birth parent, are conflicted about visitation, or have to enforce court-ordered restrictions to which the parent and other relatives object.

Evidence is mounting for models of visitation in which a mental health professional provides child-parent psychotherapy or child-parent interactive therapy. Such models focus on helping the parent identify the child's cues, understand his or her developmental capacities, practice parenting skills learned in court-ordered parenting education, and respond to the child in an appropriate manner. This is time and labor intensive but has increased successful reunification in those communities that have adopted it. Another promising model is Visitation Coaching, in which trained visitation specialists prepare birth parents for visits, help the parents stay on track during the visit, and debrief with them afterward.

## FOSTER FAMILIES

Foster families are the major therapeutic intervention and the unsung heroes of the foster care system. Most of these families are warm, caring, dedicated

individuals who open their homes to society's most fragile and needy children, taking them into their own families and nurturing them through multiple crises. Although foster parents vary in the skills they bring to caring for children, they are generally motivated by religious conviction, altruism, or personal need. They tend to be *child centered*, often having raised children of their own, and see foster care as a mission because of their love for children. Some families become foster parents as a path to adoption, although a guarantee that a child placed with them will become eligible for adoption seldom exists. Foster parents are usually married, have a middle or lower-middle income, come from tradition-rich backgrounds, are deeply religious, and have a fairly open definition of who constitutes family. A very small percentage of foster parents are same-sex couples. Almost every state allows same-sex couples to foster and adopt, although at this writing there remains at least one state that only allows one member of a same-sex couple to adopt. Approximately 5% of foster families have specialized training or skills and act as resources for severely emotionally disturbed or medically fragile children. Many states now have designated skilled homes that provide care for children with human immunodeficiency virus (HIV) infection or other complex medical problems.

Reimbursement for foster parenting varies widely. Families are paid a daily *board rate* for each child in their care. The rate, set by individual states, is determined by the child's age and health needs and the complexity of the parenting tasks. Average monthly board rates hover around approximately \$400 and are expected to cover food, shelter, personal needs, recreation, and most transportation and educational costs. A study from 2008 showed that board subsidies cover about two-thirds of the cost of caring for a child and that most foster parents "chip in" their own funds. Many agencies reimburse for some transportation (involving medical or mental health visits) and pay an additional stipend for clothing. The highest foster family board reimbursements are for children with extremely complex medical conditions or severe behavioral and emotional issues; these may exceed \$1,000 per month in foster family care. Approximately 15% of children in foster care, mostly adolescents, reside in residential or group home placements, the most costly form of care, which can cost upward of \$100,000 per child annually.

Recruitment, adequate training, and retention of suitable foster families are some of the most compelling tasks facing child welfare agencies. Agencies are supposed to provide potential foster parents with education in the areas of child development, child abuse and neglect, behavior problems, discipline, safety issues, and their roles in relation to the agency and birth families, but training is often minimal. Certification is not supposed to occur until the agency has conducted a home visit, a criminal background check, and a review of the state's child abuse registry. Agencies lack adequate staff to scrutinize foster homes carefully, and annual recertification is less rigorous than the original certification process. Several studies have shown that increased education and support for foster parents can have a dramatic positive effect on children. Currently,

there are only a few localities that have the resources for such intensive efforts. Most communities do not even require foster parents to participate in an evidence-based parenting education program before or while fostering. Although there has been an emphasis on trauma training for foster parents and caseworkers, many agencies continue to provide the bare minimum in terms of education and support.

Boundaries are blurred in the foster care system in terms of authority, responsibility, and accountability. Foster families retain the bulk of the daily responsibility for children and teens but are accountable to caseworkers, the legal system, and the birth family for the child's care. Foster parents may feel excluded from planning on the child's behalf, given that birth parents retain legal custody, child welfare agencies have authority to make decisions on behalf of the child and generate permanency plans, and courts make placement decisions. However powerless, foster families often remain the individual child's strongest advocate.

Foster parents usually have only limited information about children in their care. Placement in a foster home is often regarded as the only necessary therapeutic intervention a child needs, and agencies vary widely in the amount of guidance and services they provide to foster parents and children in their care. Foster families may be overwhelmed, and placements may fail when foster families feel isolated in dealing with a child's complex behavioral and emotional problems. Because of foster home shortages in many areas, particularly large urban centers, most homes maintain the maximum number of children allowed under regulations, further stressing a family's emotional resources. Abuse and neglect occasionally occur in foster or kinship care, and the physician needs to remain alert for signs of inadequate care.

Foster families, like children in foster care, experience multiple separations and losses as children enter and then leave their homes, often for a living situation that the foster parent deems unsuitable. Relationships between foster and birth families range from adversarial to mutually supportive. Foster parents often bear the brunt of a child's anger over a failed visit or a parent's telephone call, or they may be unjustly accused of neglect or abuse by an angry birth parent. They may feel scrutinized, but simultaneously unsupported, by child welfare staff.

## KINSHIP CARE

In the past decade, the numbers of children placed in kinship care increased dramatically (>300%). Unofficial placement with kin caregivers is more common than *relative resource care*, defined as care provided by a relative who has become certified as a foster parent. Although driven by a commitment to maintaining a child within their family of origin, kinship care providers have often made this choice under some duress and with the recognition that a member of their own family, who is often their adult child, has neglected or abused the child. Kin caregivers often are older, are poorer, and have access to fewer resources than foster caregivers. Unless they have become certified foster parents, they are not subject to the same review or oversight as foster caregivers, nor do they have access to the same supports.

Placement with a relative, however, offers significant advantages to children, the most obvious of which is that it maintains their ties with their larger family of origin, their community, and their culture. A few studies have also shown that kinship care is associated with fewer placement disruptions and, in one study, a reduced incidence of abuse or neglect, compared with placement with a nonrelative. Compared with nonrelative foster parents, relative caregivers report that children have fewer behavioral problems. Kin caregivers with marginal incomes have the option of applying for foster care certification in many states, making them eligible for foster care stipends, but with all the oversight of foster care.

### BIRTH FAMILIES

Removal of a child is a traumatic event for the birth parent. For some, the shock of the removal is sufficient to precipitate cooperation with child welfare, family court, and prescribed therapies, resulting in speedy reunification. Approximately one-half of children in foster care are returned to their birth families within the first 6 months. For other families, even the removal of a child does not alter ingrained patterns of substance abuse, violence, and child neglect.

Parents, while battling addiction, mental illness, and poverty, often have to contend with feelings of guilt, powerlessness, inadequacy, anger, frustration, and resentment when children are removed. Even though they retain legal custody, their contact with their children is constrained, with only several hours of supervised visitation per week initially. Parents may fail to show up for visitation, whether because of substance use, mental illness, guilt, the pain of separation, fear of confronting their child or children, or barriers such as transportation.

Although one of the goals of the foster care system is reunification, and although caseworkers are mandated to provide a range of services supporting this goal, some birth parents become locked in an adversarial relationship with child welfare staff, resentfully refusing all help offered. In the past, some parents effectively abandoned their children to the system, maintaining contact just sufficient to prevent termination of their rights. Many of these same parents refused to surrender their children for adoption, even when reunification was clearly not an option. The ASFA legislation has made the TPR process easier in such situations. This legislation also reinforces the concept of open adoptions, thought to benefit the child by providing some ongoing limited supervised contact with the family of origin.

### DEVELOPMENTAL AND EDUCATIONAL ISSUES

Multiple studies have shown that approximately 60% of young children entering foster care have developmental delays, especially in the areas of language, social, and self-help skills, although they have been shown to benefit from placement in a nurturing foster home and early intervention services. Before foster care placement, children and teens have experienced high rates of absenteeism, suspension, school failure, grade

retention, and multiple school transitions. Children and youth in foster care are an educationally vulnerable population that continues to perform below grade level (75%), perform poorly on standardized testing, and exhibit significant behavior issues. Forty-four percent of children and youth in foster care are in special education settings, one-half for behavioral concerns. Stable placement in foster care has been shown to result in predictable school attendance for the first time and is often accompanied by improved academic performance for younger children. A national study of 20,000 young adults who had aged out of foster care in 1998 showed that only 35% graduated from high school and only 11% went on to college or vocational school; 37% of foster teens in another study dropped out of high school. Of seniors in high school who were also in foster care, 65% said that a parent or guardian had never attended a parent-teacher conference. Teens in foster care are as likely to drop out or attain a general education degree as to graduate from high school.

### OUTCOMES FOR CHILDREN IN FOSTER CARE

Foster care and its outcomes for children remain mixed. Minority children remain over-represented in foster care. Just more than 60% of children exiting foster care were reunited with their parent or caregiver, 15% were placed with kin, 19% were adopted, 10% aged out of foster care, and the remaining 3% were mostly transferred to the care of other agencies. The overall recidivism (return to foster care) rate is 20% during the first year after reunification but approaches 30% for infants.

The children in foster care who are eventually adopted are usually adopted by their foster parent (56%) or by a member of their extended family (30%). Almost all adoptions out of foster care involve some subsidy, reflecting the child's physical health, mental health, and developmental needs. Many children also retain their Medicaid insurance, although this retention depends on laws in individual states. An adoption subsidy, once granted, continues until the child reaches 18 years of age.

Of the 102,000 children and teens residing in foster care who are available for adoption, only one-half of them have an adoptive home identified. Children awaiting adoptive homes are mostly adolescents, children considered difficult to adopt by virtue of their significant medical or behavioral problems, older minority children, or those who are part of large sibling groups.

More than 20,000 teens and young adults age out of foster care's independent living programs annually; many leave the system without family resources, although some maintain contact with their families of origin or foster families. Current child welfare practice dictates that agencies assist youth in identifying meaningful adult resources as part of the emancipation process. A small percentage (3% of adolescents) are lost to care through elopement, and a similar number become involved with the criminal justice system or are placed in long-term residential care because of

their intellectual disabilities. The outcomes of adolescents leaving foster care for independent living are very poor.

## ADOPTION

The foster family is most often the party to whom the system turns for adoption when reunification is no longer considered an option. Long-term foster care placement is no longer an option under ASFA, although some foster families make a long-term commitment to one or several of the children and teens who have been freed for adoption but for whom belonging in a *forever family* remains an elusive goal. Termination of rights severs the child's legal ties to their birth family, but not their emotional ones, and the child may be torn between conflicting loyalties to birth and adoptive families. Behavioral problems may escalate or resurface around termination or as adoption nears, as the child re-experiences rejection and loss of his or her original family. Agencies work closely with parents who choose to free children for adoption voluntarily to ease the grief and loss for both parents and children, but the child may view voluntary surrender by the parent as the ultimate rejection. On the other hand, for children who have had a limited and chaotic relationship with their birth family, adoption by their foster or kinship parents is often welcomed.

## HEALTH CARE ISSUES AND RECOMMENDATIONS FOR CHILDREN IN FOSTER AND KINSHIP CARE

Children in foster care represent a highly vulnerable, medically complex population, suffering high rates of chronic medical illness, developmental disabilities, educational disorders, dental problems, and behavioral, emotional, and mental health problems. All children in foster care should be considered *children with special health care needs*. In general, for older children and adolescents, these conditions predate placement and are rooted in their experiences of childhood trauma and loss. Prenatal drug exposure, poor maternal nutrition, genetic risks for mental health problems, and poor prenatal care lead to an increased incidence of premature and small-for-gestational-age infants. Postnatally, psychosocial deprivation, poor nutrition, maltreatment, and failure to attend to the child's health and developmental needs exacerbate problems. Limited use of preventive health services, fragmentation of health care, and underimmunization are typical of children entering foster care. Children also enter foster care with a history of complex trauma, including child maltreatment, and toxic stress that adversely affects their physical, emotional, and developmental well-being.

Studies of the health status of the foster care population have yielded fairly bleak results. Approximately 45% have at least 1 chronic medical condition, with approximately one-fourth of all children in care having 3 or more chronic problems. The most commonly encountered diagnoses include growth failure, neurologic problems, dermatologic problems, anemia and hematologic problems, respiratory problems, parasitic infections, asthma, and gastroesophageal problems. Obesity has become the major type of malnutrition

seen in foster care. Hematologic disorders, mostly attributable to anemia, are present in approximately 20% of children. Burn scars or scars from physical abuse are encountered in 10% to 15% of children younger than 12 years. Visual and hearing impairment and neurologic disorders (varying from mild motor delay to seizures and cerebral palsy) are more prevalent in this population and may be the result of prior physical abuse or medical neglect, or they may be the reason for voluntary placement in foster care. Congenital anomalies occur at higher rates than in the general pediatric population. Sexually transmitted infections and other infectious diseases, whether vertically or horizontally transmitted, are more frequent. Approximately 8% of children in foster care are high-cost patients because they are technology dependent, multiply handicapped, or heavy users of ancillary services.

After children enter foster care, their overall health does not seem to improve significantly. A recent study in New York State reported that less than 30% of children in foster care had access to preventive health services before foster care and had minimally improved access while in foster care. The high mobility of this population contributes to poor preventive health care access. The same study reported that this population accesses high-cost services, such as the emergency department and inpatient medical and psychiatric services, at very high rates. Health information on admission is almost universally lacking, and it can be difficult to identify who previously provided medical care. Neither caseworkers nor foster parents have the level of knowledge necessary to serve as the health care manager, yet the system relies on them to perform this complex task. The *Fostering Connections to Success and Increasing Adoptions Act* of 2008 now requires states to develop health care systems for children in foster care, to work with pediatricians to accomplish this, and to promote the medical home as a source of care. This process is, however, in its infancy in most states. Health systems are essential because inadequate health care management underlies the pattern of inadequate, fragmented, and occasionally redundant care received. Medicaid programs in some states limit access to health care because of inadequate financing, delays in payment, and limited numbers of medical subspecialists willing to accept payment. Some Medicaid managed care programs increase access to medical subspecialists for children in foster care but significantly reduce access to mental health care, although this is the most significant health care need of the foster care population. Complex consent and confidentiality procedures required by the foster care system often limit access to health care, delay evaluations and treatment, and confound communication among professionals. Failure to support and educate foster parents about a child's medical, developmental, and mental health needs and failure to secure appropriate treatment can lead to disruptions in placement when foster parents are overwhelmed. As states move toward the implementation of recent legislation, pediatric practitioners may have the opportunity to engage state and county officials to improve outcomes for children in foster care.

The AAP has a number of resources to help pediatric professionals in this role (Box 72-1; see also [www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america)).

## OPTIMIZING HEALTH CARE FOR CHILDREN IN FOSTER CARE

Ideally, children in foster care receive their health care in the context of a medical home. For the child in foster care, the medical home ideally includes a foster care–friendly office with providers who understand the effect of childhood trauma and loss on health, development, and well-being; education and support for caregivers in the context of such trauma; and collaboration and communication with child welfare

personnel around a child's needs. The AAP Task Force on Foster Care has developed a number of resources for pediatric professionals regarding health care for children in foster care. Resources, including *Fostering Health: Health Care Standards for Children and Adolescents in Foster Care*, are now available on a Web site, *Healthy Foster Care America* (HFCA) ([www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america)). This resource was designed for use by interdisciplinary professionals, health care providers, and families and children. Because many states have only broad guidelines governing the provision of health services to children in foster care, these detailed standards may be helpful to pediatricians advocating with foster care agencies for improved care. Unfortunately, multiple barriers still

### BOX 72-1 Guidelines for Health Care of Children Entering Foster or Kinship Care

Children entering foster care should have an admission health evaluation, which includes the following:

1. Infants and preverbal children and those with chronic or acute medical problems or on medication should be seen within the first 24 hours whenever possible. All other children and adolescents should receive a health screen within 72 hours of placement to assess and document:
  - Symptoms or signs of child abuse and neglect, with referral as needed
  - Growth parameters
  - Symptoms or signs of acute illness and use of any over-the-counter or prescribed medications
  - Symptoms or signs of chronic illness and use of any over-the-counter or prescribed medications
  - Developmental screening results and referral for evaluation
  - Behavioral and mental health screening results (focusing on suicidal or homicidal ideation or intent, history of aggressive behaviors, substance abuse or addiction) and referral for evaluation
  - Appropriate referral for emergent health issues or sexual abuse evaluation
  - Appropriate treatment of identified issues
  - Health education of foster or kinship caregiver
2. Health information gathering: an ongoing process that begins at admission to foster care
3. Comprehensive health evaluation within 30 days of placement to:
  - Review all available health history
  - Address health concerns
  - Assess adjustment to foster or kinship care, child care, school, and visitation
  - Address behavior concerns and daily schedule
  - Assess growth parameters
  - Review systems
  - Perform a developmental or educational evaluation or review of evaluation or referral for evaluation if not previously completed
- Perform a mental health evaluation or review of evaluation or referral for evaluation if not previously completed
- Perform a complete physical examination
- Screen for signs and symptoms of child abuse and neglect
- Undertake all recommended screening tests (hearing, vision, lead, complete blood count and differential, purified protein derivative, rapid plasma reagin, hepatitis B and C, and HIV)
- Administer immunizations (consider catch-up immunizations if no history is available)
- Provide age-appropriate anticipatory guidance, focusing on transition issues
- Provide appropriate or indicated treatment and referrals, including dental treatment
- Provide communication in writing of health plan to foster care agency
4. Follow-up admission assessment within 60 to 90 days of placement to:
  - Review all available health history, including results of mental health assessment, developmental and educational evaluations, and dental assessment
  - Address interval concerns
  - Document growth parameters
  - Assess adjustment to foster care, child care, school, and visitation
  - Conduct behavioral screening
  - Conduct developmental screening and review
  - Perform a focused physical examination
  - Screen for child abuse and neglect
  - Administer immunizations as indicated
  - Ensure that all referrals and recommended treatments are in process or have been completed
  - Schedule or plan next visit

prevent translation of these guidelines into accessible, effective, and efficient health care. The barriers include inadequate funding, insufficient caseworker and foster family knowledge, limited understanding of the foster care experience by health professionals, and blurred boundaries of responsibility for the health care management of this complex population. The AAP guideline for pediatricians regarding helping foster and adoptive parents cope with trauma in caring for traumatized children is also available on the HFCA Web site.

Every preventive health visit with a child in foster care ideally includes anticipatory guidance around issues specific to foster care: transition issues, visitation issues, the need for routines and reasonable expectations, the effect of prior trauma on emotional

and developmental well-being, and appropriate discipline, among others.

Recommendations for optimizing health care in the medical home and promoting healing for children and adolescents in foster care (Box 72-2) are available on the HFCA Web site and include the following:

1. The pediatrician ideally has a relationship with the foster care agency (Box 72-3) in which established methods of communication and information exchange facilitate the child's care.
2. The caseworker is the case manager, whose responsibilities include the child's health. The caseworker is responsible for obtaining appropriate releases of information and medical consents from the birth family and sharing copies with health providers, including the pediatrician. The pediatrician may wish

### BOX 72-2 Special Considerations in Caring for Children and Adolescents in Foster Care

Every health encounter in foster care requires extra diligence on the part of the physician, including the following:

- Children in foster care are screened for abuse and neglect at each health care encounter, and the physician should bear in mind that inadequate weight gain is often the first sign of inadequate parenting in a foster home.
- Children entering foster care should ideally receive a full mental health (ideally, including trauma history) and behavioral health evaluation performed by professionals in the field of mental health within 60 to 90 days of entry to foster care. If insufficient resources exist in the community, then the pediatric professional may need to be guided by a validated mental health screen, parental concerns, patient trauma history, and clinical judgment about whom to refer for fuller assessment. Periodic monitoring of mental health is encouraged in all populations, but especially those in which adverse experiences continue to accumulate. (See the AAP Mental Health Toolkit at [www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Pages/Addressing-Mental-Health-Concerns-in-Primary-Care-A-Clinicians-Toolkit.aspx](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Pages/Addressing-Mental-Health-Concerns-in-Primary-Care-A-Clinicians-Toolkit.aspx).)
- Children entering foster care should ideally receive a full developmental or educational evaluation performed by professionals in the field within 60 to 90 days of entry to foster care. If insufficient resources exist in the community, a validated developmental screening tool or information from school professionals may help the physician to decide which children will benefit from fuller evaluation.
- Children in foster care should be referred for dental care at the first health encounter or by 1 year of age.
- The physician should attend to the quality of the interaction between caregivers and children. The pediatrician may wish to relay concerns to child welfare if a caregiver lacks warmth toward a child, displays a negative affect toward the child, or speaks harshly to or about the child. A child who repeatedly looks to the caregiver for cues or seems fearful in the presence of the caregiver should be an alert of deeper relationship difficulties.
- Because of their importance in the child's life, the physician is encouraged to review recent changes in the child's visitation and contact with birth family, school attendance and performance, and participation in normalizing activities, among other issues.
- Every encounter should be considered an opportunity to immunize the child.
- The physician should maintain a well-documented health record for the child in foster care.
- The pediatrician ideally has a foster care–friendly office and offers anticipatory guidance with an additional focus on normalizing activities, predictable routines, positive parenting strategies, helping children deal with transitions such as visitation, and the effect of trauma and separation on emotional and developmental well-being, among other issues. (See [www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/healthy-foster-care-america).)
- A system for tracking health care use and compliance for children in foster care is useful for ensuring that children's needs are met and for alerting the agency when noncompliance exists.
- Referrals should be made promptly when an issue is identified.
- Children leaving foster care benefit from a discharge health visit that includes their new caregiver. This visit is an opportunity to summarize health information and transfer it to the new health care provider and caregiver or to the individual patient who is aging out of foster care.
- Systems for information exchange improve coordination of care between the foster care agency and the physician.
- Up-to-date health summaries that include diagnoses, recommended treatment, and follow-up enable the caseworker to keep the health plan current.
- The foster care agency should provide the physician with as complete a health history as is available for the child, copies of appropriate consents and releases, notification of changes in placement or caseworker assignment, and notification of referrals made by the agency shortly after the child enters foster care.

**BOX 72-3 Pediatrician's Role in Caring for Children in Foster Care**

This list is intended to show 2 possible separate, but overlapping, roles for pediatricians. Of course, the pediatrician who is the medical home health care provider may choose to serve any or all of the consulting roles.

**CONSULTANT ROLE FOR CHILD WELFARE AGENCY REGARDING CHILDREN IN FOSTER CARE**

1. Ensure that the foster care agency understands all AAP standards for health care.
2. Help the foster care agency ensure that each child has a medical home with access, insurance, consents, continuity, and other avenues of support.
3. Develop systems for communication and information exchange among caseworkers, mental health professionals, the court system, other health care providers, and school personnel.
4. Provide or refer to health education resources for foster parents, caseworkers, the court system, attorneys, and school personnel.
5. Develop systems for merging health information and planning into child welfare permanency plan.
6. Develop systems for transitioning health care when the child or teen transitions or leaves foster care.
7. Develop systems for tracking patients that include information on their health needs and data, monitoring outcomes, and any other information.

**MEDICAL HOME PROVIDER ROLE FOR CHILDREN IN FOSTER CARE**

1. Deliver care by the AAP Foster Care Standards. Identify and attend to the child's health care needs.
2. Accept patients in foster care and provide a medical home for them.
3. Communicate and coordinate with caseworker, foster parents, school personnel, subspecialists, and the court system regarding individual patients in foster care.
4. Educate the foster parents, caseworkers, or anyone else involved regarding the child's health care needs.
5. Advocate on behalf of patients in foster care to ensure that health care needs are met.
6. Share health information and plan for the child with the caseworkers, foster parents, court system, and older children in foster care.
7. Ensure that information on the patient is transmitted to the appropriate professionals when the patient transitions out of foster care or from one foster care placement to another.
8. Monitor and track the patient's health needs and care.

to become familiar with the foster care agency's guidelines regarding consent and confidentiality. The foster care agency should have the authority to provide consent in the absence of the birth parent. Certain adolescent health issues, such as pregnancy, sexually transmitted infections, birth control, and substance abuse, are governed by separate confidentiality laws in most states.

3. Gathering health information is a challenging task. The caseworkers, who should have contact with the birth parents, are invaluable in this respect, although they may also be stymied by a dearth of contact and of records. A standardized health information form can help with information collection. The pediatrician may have access to information from prior health providers, schools, Regional Health Information Organizations, and immunization registries. In addition to the usual health history, information that should be sought includes prenatal and perinatal history, developmental history, history of early intervention, mental health history including the use of psychotropic medications, growth curves, immunization records, risk factors for HIV, accounts of other vertically transmitted infections, allergies, chronic illnesses, and medications. For older children, additional information should also include any educational or mental health problems. A paucity of such information may exist because the child may not have received adequate services before foster care or may have had multiple providers.

4. Children entering foster care should have a series of health care encounters over the first 3 months (see Box 72-1). Multiple encounters during this transitional phase often reveal more than one isolated evaluation.
5. Routine primary preventive health care should be scheduled according to AAP guidelines, although experts recommend that children in foster care have more frequent monitoring visits because of their health needs and high mobility. Ideally, infants in foster care should receive monthly visits until age 6 months. Toddlers should receive a health visit at 21 months to monitor development and emerging behavior concerns. After age 2 years, children should have a health encounter between annual preventive health visits until they exit foster care.
6. Comprehensive preventive health care for the foster care population requires diligent effort on the part of the physician. Extended appointment slots and a tracking system are strongly suggested. Ideally, the caseworker should inform the physician about changes in placement and casework assignment and about any referrals made by the caseworker. The physician, in turn, provides the caseworker periodic updates around health care encounters to keep the health plan current.
7. Approximately 70% of children and adolescents entering foster care have been physically abused, sexually abused, or neglected. Physicians should be

familiar with the signs and symptoms of abuse and neglect and should screen all children and teens at the time of admission to care. Children with suspected sexual abuse should be referred to a center specializing in child sexual abuse, if one is available, to prevent the trauma of repeated interviews and examinations. Monitoring for abuse or neglect at every health encounter is part of the pediatrician's responsibility and includes addressing concerns about the adequacy of parenting in a foster home. Some red flags for poor care include inadequate weight gain in a foster home (often the first sign of neglect); lack of warmth between the child and the caregiver; hypervigilance by the child around the caregiver; and caregiver reluctance to allow a private conversation between the child and the pediatrician. In addition, ancillary office staff may sometimes witness and should be encouraged to report concerning caregiver-child interactions to the physician. Although poor compliance with recommended health visits may represent scheduling difficulties, it is often a sign of poor overall care in a foster home.

8. Children in foster care have a high prevalence of dental problems, especially dental caries and malocclusion. Changes in placement may result in a lapse in dental care; therefore, continued monitoring of dentition and reminders to foster parents about the importance of routine dental care are important. Referral for dental care should begin at age 1 year.
9. Children entering foster care tend to be underimmunized, even compared with other poor children, and every health encounter should be viewed as an opportunity to immunize a child in foster care.
10. The underuse of routine preventive health care services before foster care placement implies a deficiency of screening for lead, iron deficiency anemia, and tuberculosis exposure. Many children in foster care reside in or have resided in older housing stock, and pica is a commonly encountered behavioral issue in this population, increasing the risk for elevated plasma lead levels. Poor nutrition before foster care places children at risk for iron deficiency anemia and other micronutrient deficiencies; thus, physicians should obtain plasma lead levels and screen all children younger than 6 years for anemia at least annually. Obesity is now a prevalent form of malnutrition, and appropriate diet and exercise should be addressed with caregivers and children. Children entering foster care have an overall obesity rate of 27%. Of obese children who remain in foster care for at least 1 year, only 12% lose weight in care, whereas 7% gain weight. Youth residing in congregate care have higher rates of obesity than other children in care. Menstruating adolescent girls should have annual hemoglobin screening. Universal tuberculosis screening is recommended using the PPD test at admission and every 3 to 5 years thereafter because children may have had high-risk exposures before foster care and visit in high-risk situations (eg, jail) while in foster care. Hemoglobin electrophoresis should be considered in at-risk children with no documentation of sickle cell screening at birth.
11. Maternal lifestyles during pregnancy, including substance abuse and promiscuity, place children in foster care at increased risk for a variety of vertically transmitted infectious diseases, including HIV, hepatitis B and C, congenital syphilis, and herpes. Every child placed in foster care should be screened for these infections early in placement. Up to 80% of young children placed into foster care are at high risk for vertically transmitted HIV infection, but fewer than 10% are screened because of the complexities of risk assessment, obtaining informed consent, and confidentiality barriers. Guidelines for HIV risk assessment and screening of children in foster care vary from state to state. Some agencies use risk-assessment tools to determine a child's risk for HIV infection, although the accuracy of such tools depends on the birth parent's availability and truthfulness. In general the biologic parent retains the right to consent to testing or not, unless the child has been freed for adoption or parental rights have been terminated. Agencies vary in their policies regarding consent procedures when a parent declines screening but the child meets high-risk criteria. Identifying children who are HIV positive is critical to appropriate medical management, including pneumocystis pneumonia prophylaxis, modification of the immunization schedule, and early antiretroviral therapy. Pediatricians may wish to become familiar with the HIV policies in their state and promote appropriate risk assessment and screening for the individual child.
12. Adolescents in foster care also represent a high-risk group for HIV and other sexually transmitted infections, because of either unprotected sex with multiple partners or prior sexual abuse. In general, adolescents in foster care are allowed by law to give consent for HIV testing, unless they are cognitively impaired. Confidentiality laws vary, however. In some states the adolescent has the right to designate who has access to HIV-related information, whereas in others, social service agencies and their representatives have access to such data on any child in their care and custody, including adolescents. Obviously, pediatric professionals need to provide detailed anticipatory guidance around healthy and safe sexuality. Screening for gonorrhea and chlamydia is recommended at admission and at each preventive health care visit. Testing for other sexually transmitted infections should be considered based on history and local epidemiology.
13. Because of the high prevalence of developmental (60% of children <6 years) and educational (45% of children >6 years) problems, screening with the use of standardized instruments is recommended at the time of the comprehensive admission visit, with periodic reassessments at preventive and monitoring visits. Ideally, all children receive a full developmental-educational evaluation within 3 months of placement, but lack of resources

usually precludes this. Developmental delays are most prevalent in communication, social-emotional, and cognitive skills. With services and an appropriate home environment, many children make developmental strides in foster care. For children who are undereducated because of a lack of schooling, catch-up can be dramatic with increased school attendance, although learning disabilities, behavioral disorders, and limited cognitive ability remain major challenges. Upward of 40% qualify for special education services or an educational plan. Some children in foster care qualify for special education for emotional rather than cognitive concerns, given that attentional difficulties, poor impulse control, and aggressive behaviors often preclude placement in a regular classroom. The high prevalence of language disorders (50% to 60% of preschool children) implies that universal hearing and speech evaluations of toddlers and preschool children may be beneficial in identifying children who would benefit from such services. The primary care physician and caseworker ideally maintain contact with the case manager for developmental-educational services and receive copies of all evaluations. Pediatric professionals may be asked to medicate children for presumed attention deficit/hyperactivity disorder (ADHD) but should be aware that inattention, hyperactivity, and distractibility may be behavioral manifestations of prior trauma, anxiety, or depression rather than ADHD and proceed cautiously. (See Chapter 62, Psychotropic Medications in Primary Care Pediatrics.)

14. Mental health care is the greatest health care need of most children in foster care. The prevalence of severe disturbance ranges from 35% to 85%. Children in foster care use both inpatient and outpatient mental health services at rates 15 to 20 times those of other children of similar backgrounds but are still thought to be underserved. Oppositional defiant disorder, ADHD, attachment disorder, and anxiety disorders are the most commonly cited mental health diagnoses for children in foster care. One study in the Midwest reported that 45% of teens in foster care used alcohol or illicit substances in the prior 6 months, whereas 49% acknowledged past use and 35% met criteria for a substance abuse disorder. Those at highest risk are those with conduct disorder or post-traumatic stress disorder and those residing in independent living situations. This may not reflect actual use because youth may have under-reported or the reporting population may not have been adequately representative of all teens in foster care. What is known about the effect of childhood trauma suggests that substance abuse is often a form of self-treatment. Professionals experienced in foster care think that the prevalence and severity of mental health disabilities have increased dramatically in the past decade, although some of this may be attributed to heightened awareness among child welfare, pediatric, and mental health professionals. The burden of early childhood trauma and toxic stress predating foster care

placement is enormous. Entry to foster care and placement in a good home environment may remediate emotional disorders or may exacerbate them because of the trauma of separation from families and the emotional turmoil of living as a child in an uncertain world. Although marijuana is the most commonly abused drug among those in foster care, youth using addictive substances may experience acute withdrawal at entry to foster care. Thus, physicians should screen for emotional and behavioral issues using standardized instruments at admission and at each preventive health and monitoring of care visit. Every child in foster care should ideally have a full mental health evaluation by 2 years of age or within 3 months of placement. Children with newly identified mental health or behavioral issues should be referred to appropriate mental health services, ideally with pediatric mental health providers who use evidence-based, trauma-informed practice. Those children previously involved in the mental health system, including those for whom psychotropic medications have been prescribed, should have a thorough review of the mental health treatment plan, ideally through direct contact with the mental health professionals who previously assessed the child and who prescribed the medication. All children in foster care have to deal with ongoing separation and loss issues, as well as feelings of anger, sadness, rejection, powerlessness, alienation, and guilt. Even children who do not initially seem to need mental health services should be rescreened at intervals to assess for changes in their emotional well-being. Some of the common stressors that upend the lives of children in foster care include inconsistent visitation, resumption of regular visits after a prolonged lapse, cessation of visitation, incarceration of a parent, illness of a foster parent, and being freed for adoption. These critical junctures are times at which resumption of lapsed counseling or increased frequency of counseling visits is beneficial. It may also be challenging for mental health professionals to know which of a child's parents (foster, birth, or kin) should be involved in therapy with the child. The California Evidence-Based Clearinghouse maintains a list of evidence-based therapies for children in foster care and their caregivers ([www.cebc4cw.org](http://www.cebc4cw.org)).

15. Many foster families have a wealth of childrearing experience, but the physician should not presume that knowledge about child development, behavior, discipline, safety, and parenting a traumatized child are adequate. Anticipatory guidance should be a routine part of well-child care and should include issues specific to foster care, such as behavior problems related to visitation and the permanency planning process, significant sleep disorders, confused loyalties, attachment, violence, and coercion. Adolescents should be counseled not only about safe behaviors but also about healthy activities, planning for their future, and developing relationships with adult mentors. Many teens in foster care, fearing yet another disappointment, have exhausted their capacity to

attach to a parental figure, and families need to be offered guidance in promoting attachment relationships with teens in foster care. Pediatric professionals can help foster parents understand the teen's emotional world while supporting an authoritative parenting style. Support for foster families and older children in foster care around transitions and other stressors can stabilize a foster care placement for a child.

16. All medical information, unless specifically prohibited by law, should be shared with the child's caseworker and foster parent and, when not disallowed, with birth parents in appropriate lay language. The caseworker has the responsibility for communicating the information to the birth parent in the likely event that the parent was not present at the medical visit. If possible, the physician should provide a written summary of each health encounter, including the assessment, treatment plan, and any scheduled follow-up. Caseworkers are required to have at least semiannual *Child and Family Service Reviews*, during which health information can be incorporated into planning for the child.
17. In caring for a child in foster care, the primary care physician might sometimes need to assume the role of advocate for appropriate health care for the child.

## PSYCHOTROPIC MEDICATION

The use of psychotropic medication has become controversial in the foster care population. Studies show that children and teens in foster care are more likely to be on psychotropic medications than peers not in foster care. They are also more likely to be on multiple medications and sometimes on multiple medications from the same class. Studies also indicate that psychotropic medications may not match the major symptom of concern or diagnosis. At least 2 states, Texas and New York, have developed comprehensive guidelines regarding the prescription and management of psychotropic medications in the foster care population, and the reader is directed to these or their individual states for further information. In general, psychotropic medications should be used as part of a comprehensive mental health treatment plan and are best prescribed for patients in foster care by a qualified pediatric mental health professional or a primary care physician with extensive foster care experience. A detailed health history, including mental health, behavior, development, trauma history, medication use, social and family history, and a full mental health evaluation should be obtained before beginning medication. Therapy should be initiated with a single agent in the lowest dose for a specific and appropriate mental health diagnosis. Dosage increases should be gradual and closely monitored for efficacy and side effects. Single-agent therapy should be used whenever possible. Close monitoring is the essence of good care for children and teens who are prescribed psychotropic medication. Pediatric professionals also need to be acutely aware that not every child in foster care who presents with school or parent concerns of hyperactivity and inattention has ADHD because such

behaviors may be a manifestation of early childhood trauma experiences. Caution should be exercised before instituting any psychotropic medication. Referral to mental health professionals for evidence-based, trauma-informed mental health evaluation and services is the ideal initial intervention for the child or teen in foster care presenting with emotional and behavioral problems. (See Chapter 62, Psychotropic Medications in Primary Care Pediatrics.)

## SUMMARY

Children and adolescents removed from their families for reasons of health and safety enter foster or kinship care having experienced multiple adversities and trauma that negatively affect their health and well-being. As a result, these children and adolescents have a high prevalence of medical, mental health, developmental, educational, and dental conditions. Pediatricians should use foster care as a window of opportunity in which the child or teen can heal. The pediatrician can provide the medical home while the child or teen is in foster care, following recommended standards of health care to identify and treat all of the child's health needs. The pediatrician should be proactive in engaging child welfare agencies to ensure that health planning is integrated into the child's permanency plan in a meaningful way. Pediatric professionals also have a role in educating child welfare professionals, foster and kinship parents, birth parents, and youth about health issues and in advocating for and coordinating health care to this vulnerable population.

## ACKNOWLEDGMENT

The authors gratefully acknowledge the children and families they serve for their inspiration, and the staffs of Starlight Pediatrics and Child Welfare for their compassion, dedication, and caring.

## Chapter 73

# CHILDREN IN THE JUVENILE JUSTICE SYSTEM

Robert E. Morris, MD; Evalyn Horowitz, MD

## HISTORY OF THE JUVENILE JUSTICE SYSTEM

Policies and regulations for juvenile detention and rehabilitation in the United States have been refined, then redirected toward newer philosophies, and then returned to older ways. Today's methods for directing behavior and those of 1910 are not unlike. A review of this history provides insights into the opportunities and challenges physicians experience today in interacting with the juvenile justice system.

Under English law, parental control was primary. In 1797, the first New York penitentiary opened. Because the state presumed its potential was to provide rehabilitation, juveniles were brought to criminal court. Community groups began lobbying for children to be

handled separately from adults, and, in 1824, the first House of Refuge for delinquent children was founded in New York. Shortly before the Civil War, in 1851, a separate detention for children younger than 12 years was founded.

The Civil War brought immigrants, poverty, violence, and chaos to the United States. Parents worked long hours, and children ran the streets, causing passage of disorderly conduct laws and more incarceration of youths. Children older than 7 years were housed with adults in jails and prisons. In 1875, the Society for the Prevention of Cruelty to Children was formed, defining child neglect and holding parents responsible. By 1892, a separate juvenile court system was founded.

With the Progressive Era of US history (1900 to 1918) came women's suffrage, child labor laws, and the 8-hour workday. Journalism and political satiric cartoons became a tool for public persuasion, and psychological theories for managing children flourished. These forces helped to shape the rights of incarcerated juveniles, and society began to feel responsible to reform youthful offenders before their criminal activity was entrenched or strengthened through incarceration.

Over the next 75 years, juvenile justice law was honed. Incarcerated girls were separated from boys, and their housing was improved. In most cases, juvenile hearings were conducted apart from adult courts, and proceedings were considered civil rather than judicial cases.

In the late 1960s, in *Kent v the United States*, it was decided that the informal process of determining whether a juvenile should be tried in juvenile or adult court failed to provide sufficient due process protection for children. A year later, an Arizona juvenile court placed a sentinel youth—the Mr Gault case—at 15 years old, in detention until age 21 years for a status offense. (A status offense is behavior that is unique to the juvenile status, such as truancy or running away.) On appeal, the US Supreme Court held, based on Article 5 of the Bill of Rights (ratified in 1791) and the 14th Amendment (ratified in 1868) regarding due process, that children had a right to receive fair treatment under the law, including the following rights:

- To receive notice of charges
- To obtain legal counsel
- To confront and cross-examine their accuser
- To avoid self-incrimination
- To receive a transcript of the proceedings
- To appeal

The 1970s brought several new developments. The 1970 case *In re Winship* held that when a juvenile is held responsible for criminal behavior, the previous standard of a *preponderance of evidence* (ie, the facts indicate the juvenile's behavior was "likely" to be true) now rose to a standard of *beyond a reasonable doubt* (ie, the evidence must be proved beyond any other logical explanation, similar to adult law). The 1971 case *McKeiver v Pennsylvania* found that juveniles charged with a criminal law violation and adjudicated in juvenile court are not entitled to a jury trial. In 1974, Congress passed the Juvenile Delinquency Prevention and Control Act, providing federal funding to states

with community programs to discourage juvenile delinquency. The law created the following:

- The Office of Juvenile Justice and Delinquency Prevention
- The Runaway Youth Program
- The National Institute for Juvenile Justice and Delinquency Prevention

The law required separation of "young and impressionable" juvenile delinquents from convicted adults. Part of the rationale behind the separation of juvenile and adult offenders was the evidence that youth learned to behave as more skillful criminals.

By the late 1980s, violent crime rose, peaking in 1994. Highly publicized shootings and shocking crimes by juveniles led citizens to fear that, for some juveniles, violence was a way of life. Retrospectively, it seems media claims greatly exaggerated the role of juveniles in perpetrating crime. In response to this perception of a crime wave, legislation swung back to "get tough on crime," and the Juvenile Justice Act was amended, allowing states to try younger juveniles as adults for certain violent crimes with resulting lengthy prison sentences. The juvenile justice system became increasingly similar to the adult criminal justice system, reflecting the sentiment that children who commit serious crimes must be held accountable and punished for their crimes, not just "reformed."

Throughout the 50 states, correctional facilities for children, much like those for adults, have vastly different infrastructure and focus. Beyond simply corralling children with aberrant behavior, their management points toward different goals, from simple containment, to punishment, to attempts to model nurturing and rehabilitation. Some systems are centralized and run by the state, including both preadjudication and post-adjudication facilities. Other states have decentralized systems, allowing counties or other jurisdictions to presort and house juveniles during preadjudication, as determined appropriate by the local courts. In nearly all states, depending on age, a youth may be remanded to adult court for certain serious crimes.

## PROCESSING CHILDREN THROUGH THE JUVENILE JUSTICE SYSTEM

The arresting officers are the first "judges" of what is best for the child and community, dealing with non-violent crime based on their best judgment. The officer may issue a "warning" and accompany the child home to discuss with the parents, usually maintaining a record of the contact. Or, the officer may take the child to the police station and ask the parent to come there to discuss the situation.

In cases in which the child does not have a parent or guardian who can or will control her, resides in a house that is not fit to live in, is abused or neglected, or is threatening persons or property, the child may be placed in a community shelter or foster care. For more serious crimes or for a reoffense, the child may be sent to a juvenile hall that generally holds preadjudicated youths; the hall may also be used for short-term incarceration as a punishment or deterrent to further offending or for placement when other release settings have failed.

If the child's offense leads to more than an officer's warning, variable legal processes occur, usually culminating in a juvenile court hearing. Children may not be incarcerated for status offenses. More serious offenses irrelevant to age range from minor offenses such as petty theft or property destruction to more serious crimes involving violence, bodily harm, sexual offenses, and other felonies.

Before disposition, referred to as the hearing, an evaluation of the child is usually performed by a social worker or probation officer who recommends to the judge the appropriate disposition of the case. This may include structured assessment tools, such as the Youth Assessment and Screening Instrument (Orbis Partners, Ottawa, Ontario, Canada); a review of family and school history; mental or physical health records; past criminal history; and statements from parents, friends, teachers, faith leaders, or the victim, plus the youth's own statement. At this point, it is important for the youth's physician to provide records, to support and encourage the parents and child, and to make suggestions about actions parents or community members may take to advocate for the child and to provide support and control of the child after release.

At the disposition hearing, the sentence depends on the offense and the state in which the crime occurred. The child may be released to the parent or guardian, community service may be required, and there may be ongoing supervision by a probation officer, social workers, or other youth workers, or multisystemic therapy. A youth on probation in the community may be required to attend a special, segregated school. Courts often order individual, group, or family counseling, structured after-school programs, or weekend or other short-term detention in a county restricted, locked facility. If there is a splintered or unsupportive family situation, the youth can be made a ward of the court, allowing the judge to control the care in an out-of-home or locked setting, assisting with the treatment and guidance of the minor and limiting or ending parental control.

Children who reoffend—in some cases, those who are involved in gang activity or who have little or no family support—may then be placed in a community juvenile “jail” or “ranch.” As noted previously, these facilities can be centralized (regional, or even state run) or community centered and may involve schooling. Depending on the offense, detention may vary in duration, with eventual release to family or foster care on probation.

States have developed increasingly more severe programs for violent or recalcitrant children (eg, high-discipline or “boot” camps). These military-like work camps seek to provide a highly structured environment with the aim of instilling responsibility and self-discipline. Such programs have failed uniformly, sometimes with tragic consequences. One such example was the death resulting from staff neglect of a 14-year-old boy sent to a Florida boot camp for trespassing at a school—a probation and parole violation related to a previous charge, but itself a relatively minor offense. After this 2006 episode, the Florida boot camps were closed.

There are far fewer resources and less discretion in adult courts, whose primary goal is to punish offenders and protect society. If a child is remanded directly to adult criminal court because of repeated crimes or a serious crime and convicted in a jury trial, the youth will receive an adult sentence, including possibly life without parole in a case of murder. This sentencing practice is currently being challenged in the Florida supreme court.

## HEALTH CARE IN JUVENILE JUSTICE FACILITIES

In the 1970s, congressional attempts at health care reform called for standards of care throughout the health care system, leading the American Medical Association (AMA) to investigate health care standards in correctional institutions. The AMA found a lack of standards, and this resulted in the development of correctional health care standards by various national organizations. By the 1990s, medical, dental, and mental health standards became formalized for correctional institutions of all sizes and in all jurisdictions. However, accreditation and adherence to the standards is voluntary. Often, compliance with standards is forced on states or jails through lawsuits brought by federal authorities or prisoner rights organizations.

Health care is considered a universal right within the United States for all incarcerated persons. In most cases, the physicians are caring and resourceful and may receive special certification as correctional health care workers. In those facilities that have chosen to undergo accreditation, the care often exceeds community standards. Tools for rationale of care (see *Tools for Practice* at the end of this chapter) have been developed by these organizations in collaboration with the AMA and with members of the recognized certification boards. For example, the Institute for Medical Quality in California ([www.imq.org](http://www.imq.org)) in conjunction with the California Medical Association and the National Commission on Correctional Healthcare ([www.ncchc.org](http://www.ncchc.org)) regularly network with physicians in updating their published guidelines for correctional medical, mental health, dental, and administrative functions. In some facilities, the physicians are contracted through private correctional health care corporations. If these companies do not maintain the standards of accreditation, they may lose their contract or can be fined by the governmental organization responsible for the facility.

The facility health care workers may be on site for a portion or the entirety of the day, depending on the size and population of the facility. It is well known that one poor outcome will cause years of financial and political upheaval for the facility; thus, the correctional administration generally facilitates access to health care, enabling the incarcerated individuals to receive appropriate health benefits. However, in some institutions, because of budget, culture, and lack of oversight, health care may be “doled out” in parcels. Federal Medicaid rules currently prohibit payment for the incarcerated inside their facilities, and many private insurance companies also decline to cover care of the incarcerated; thus, health care costs can strain the

budgets of the governmental jurisdiction responsible for the facility. More assistance, although not uniformly, is offered for hospitalizations, but not for urgent care or emergency visits. Difficulties in providing care often occur because of insufficient internal staffing during lean funding years and when outside specialty services are needed. Specialty health care outside the facility is expensive, even though fees are often discounted: inmates may be seen as threatening to the outside physicians' other patients, and payment to providers can be slow. For these reasons, some private specialty physicians refuse to see prisoners in their practices. University or public facilities often become the default care providers. In the absence of mandatory national adherence to accreditation standards, variability in quality of care for small, decentralized, and state-run juvenile detention centers persists.

Recently, a series of initiatives has taken juvenile detention into the "case management" realm in many parts of the United States. Behavioral therapy with preinterment and postinterment options, including counseling, group homes, work camps, and locked schools, has been considered part of juvenile justice. Therapeutic interventions, such as cognitive behavioral therapy, multisystemic therapy, functional family therapy, or dialectical behavioral therapy, attempt to redirect erring children to a more productive lifestyle. In the past decade, attempts were made to classify these programs by effectiveness, with some recent decreases in overall juvenile incarceration. The states have various levels of commitment. One example is the Impact program in Boulder, CO, which uses evidence-based motivational and behavioral intervention skills to engage clients in treatment to stabilize their mental health and substance abuse. Other states have no apparent interventional involvement beyond physical incarceration. Community development of youth programs involving local mental health, recreational, and social service workers have the potential to be plausible rehabilitation programs.

The concept of *restorative justice* involves reciprocal relationships between the offended community and the youth offender, who is required to engage in activities to restore the community to its preoffense status. In return, the community takes some responsibility for rehabilitation and care of the youth.

## IDENTIFICATION OF YOUTHS AT RISK FOR FUTURE DELINQUENCY

Delinquent children rarely begin to offend without an early history of maladaptive behavior, often beginning before age 12 years. Behavioral problems are often present for at least 5 years before coming to the attention of juvenile courts; in one study, one-third of offenders were diagnosed with disruptive behavior by age 13 years. Specific professional help is rarely provided to these children.

Many factors may contribute to later delinquency. In early life, these may include fetal complications, brain injury, toxic exposures to chemicals, experiences of violence in the environment, physical or mental abuse, difficult temperament, and hyperactivity. In addition, a wide variety of pathologic family structures

and functions may contribute to future delinquency. Toddlers and older children who exhibit aggression, repeated lying, risk taking, lack of empathy, or animal cruelty, and those whose parents practice harsh, erratic discipline are at risk for later delinquency. Substance use disorder, depression, victimization, and exposure to violence are often proximal to overt delinquency. Problems at school, peer rejection, association with deviant peers, unemployment, school dropout, and residence in neighborhoods with gang warfare, high rates of violence and crime, prostitution, or visible illegal substance or alcohol use compound the risk for delinquency. When children are carrying weapons, dealing drugs, or involved in gangs, their behavior becomes obviously delinquent. The pediatrician who is alert to risk factors can make early referrals to programs that work to prevent later delinquency. A number of "TIPPS" for assessing youth at risk for delinquency can be found in the American Academy of Pediatrics (AAP) publication, *Addressing Mental Health Concerns in Primary Care: A Clinician's Toolkit*. Chapter 34, Promoting Mental Health. This discusses promotion of mental health, surveillance of children and families for mental health problems, and psychosocial screening of children and their families. Chapter 139, Disruptive Behavior and Aggression, offers clinical guidance for the care of children with disruptive behavior and aggression. Children also benefit from evaluation and appropriate treatment of traumatic stress syndromes, as many had experienced horrific situations before becoming incarcerated.

Because there is evidence that very early childhood experiences have profound and long-lasting effects on an individual's behavior throughout life, programs early in life, even during the prenatal period, may be the most effective interventions to provide protection from developing delinquency. Olds and others developed a model program of home visits by trained public health nurses; these visits begin during the prenatal period and continue until the child is 18 months old. Follow-up conducted years after the program, in some cases 20 years later, has shown multiple benefits for these children, including significantly reduced delinquency and improved school outcomes compared with controls.

A Chicago-based program that provided an enhanced grade school experience and comprehensive family services from kindergarten through third grade resulted in higher rates of school completion, more college attendance, and fewer felony arrests compared with the control group. This intervention began later in life and had fewer positive effects compared with the early childhood nurse visitors. The Rand Corporation has published information about a number of effective preschool programs.

Pediatricians faced with disruptive children who are living with dysfunctional families with overly punitive parents or families suffering from major disruptions may benefit from referral to a parenting program. These have a number of titles, including New Beginnings, Positive Parenting, and Parent Training programs. Chapter 61, Psychosocial Therapies, provides a list of evidence-based programs for young children with social-emotional problems and their families.

Children who have begun to offend against laws are more likely to become involved in the juvenile justice system, which will largely determine both sanctions and rehabilitation programs to which they are referred. Some programs include outpatient therapy. For example, multisystemic treatment of antisocial behavior in children and adolescents is variably available in the United States. The treatment uses trained case managers and their supervisors to evaluate the challenges facing the child and family. Plans are developed in conjunction with the family, instituted, and evaluated, usually over a 3- to 5-month period. The program is action oriented, with a solution for each problem. For example, if the teenager is not getting to school, a person—relative, coach, or neighbor—is identified to be responsible for getting the youth to school. Curfew problems could be addressed by engaging the youth in appropriate evening activities. Individual cognitive behavioral therapy, drug counseling, and effective parenting training are often part of the program. The case manager should be available by phone 24 hours a day for crises. A team of several case managers and their supervisors meets weekly to address successes and failures. Family meetings with the case manager are conducted at a time convenient for the family. Under some circumstances, the child's pediatrician may be asked to participate; for example, there could be a health condition that affects the youth and requires optimal medical management so that the youth can regularly attend school.

A number of states and local jurisdictions have programs aimed at young offenders 10 to 12 years old. All programs involve case managers and provide integrated services (see Box 73-1).

#### **BOX 73-1 Typical Services Offered by Intensive Outpatient Rehabilitation Programs Provided to Young Offenders**

- Crisis management services
- Comprehensive assessment of all aspects of the child: physical health, mental health, substance abuse, school functioning, family economic problems or strengths, vocational needs, family and social functioning
- Skills training for youth and family
- Cognitive problem solving
- Self-control methods
- Behavior cognitive training
- Family training
- Tutoring
- School involvement
- Adult role models

From Burns BJ, Howell JC, Wilg JK, et al. Treatment, services and intervention programs for child delinquents. Child Delinquency Bulletin Series March, 2003; NCJ 193410. Washington DC: US Department of Justice, Office of Justice Programs, Office of Juvenile Justice and Delinquency Prevention. Available at: [www.ncjrs.gov/html/ojjdp/193410/contents.html](http://www.ncjrs.gov/html/ojjdp/193410/contents.html). Accessed October 30, 2015.

Several other evidence-based outpatient programs are therapeutic foster care, dialectic behavior therapy, functional family therapy, and motivational enhancement therapy; these are available for children with certain mental health diagnoses or who have committed certain types of crimes. These therapies are sometimes used while the children are incarcerated.

#### **Children Incarcerated for a First Offense**

For more involved delinquents who are incarcerated, rehabilitation becomes part of the therapeutic milieu. Generally, smaller institutions with only 25 to 30 children have better outcomes and less violence, as demonstrated by the Missouri State System and others.

A variety of theoretical frameworks support programs for incarcerated children. A widely accepted set of principles that guide rehabilitation programs for incarcerated children involve attention to the criminogenic risks of each youth (see Box 73-2). Evidence shows that the criminogenic risks are the most important issues to address during rehabilitation, while excluding other factors often found in delinquent youth that research shows are not relevant to reducing recidivism. When addressing criminogenic risks, counselors must consider the degree of risk to reoffend (ie, high-risk youths, defined as those with more criminogenic risk factors in their history, require more intensive services). Also important during rehabilitation are the principles of responsivity (ie, interactions are tailored to learning styles and abilities) and professional override (ie, trained professional staff make decisions based on the current situation) (see Box 73-2). A logical inference of this theoretical framework supports the notion that low-risk youths require little or no services because they are unlikely to reoffend.

Despite the enthusiasm for using this criminogenic risk evaluation during incarceration, Lipsey recently reported on a meta-analytic overview designed to assess the factors that make up effective rehabilitation interventions. He found that the criminogenic risk principles were important first steps, but that programs were most effective if done in the child's community as opposed to during incarceration. The data showed that the best interventions included cognitive behavioral therapy, mentoring, and group counseling. Not surprisingly, high-quality programs worked best for high-risk offenders, and these programs were usually research or demonstration programs. Evaluations of

#### **BOX 73-2 Criminogenic Risks for Youths to Reoffend**

- History of antisocial behavior or low self-control
- Personal attitudes, values, or beliefs supportive of crime
- Procriminal associates and isolation from anticriminal peers and role models
- Current dysfunctional family features
- Callous personality factors
- Substance abuse

routine practices generally had about half the effect of high-quality programs because they were not conducted with fidelity to the original program.

Aggression is a significant issue for many incarcerated children. Aggressive replacement training uses a number of short problems that illustrate issues in moral reasoning, anger control, or prosocial skill building. Small groups of youths are guided through these exercises by trained staff over about a 10-week period.

A complete discussion of various rehabilitation strategies in use throughout the United States is beyond the scope of this chapter. However, many physicians believe that all effective interventions must, at a minimum, address the intrinsic and extrinsic factors known as criminogenic risks to effectively reduce the risk for reoffending.

Pediatricians are unlikely to be extensively involved in the lives of children who are incarcerated. However, the parents may turn to their child's doctor for advice. Alternatively, the youths may form an attachment to physicians or therapists after repeated or extended incarcerations, especially if these doctors also work outside of the juvenile detention facility in the community. Because many youths (as many as 50% or more) have co-occurring mental health and substance use disorders, the National Commission on Correctional Health Care Standards for Health Services in Juvenile Detention and Confinement Facilities mandate that youths with these co-occurring disorders should be assessed and managed by appropriate physicians while in detention. The parents should be urged to advocate for treatment of these disorders while their child is incarcerated and prepare to continue treatment for the youth after release. Parents, even if they are geographically far removed from their child, should work to maintain contact with both their child and the staff at the correctional facility. When a child with a substance abuse disorder is released, the court will often mandate that the child attend a substance abuse treatment program that the court or jurisdiction will reimburse. Generally, it is the probation or parole officer who is responsible for ensuring that the youth attends any mandated treatment programs after release.

Failure to ensure continuing care after release remains a major problem for incarcerated children. When pediatricians become aware that their patient will soon be released, they should contact the facility's medical department to plan for a smooth transition back to community care. The youth's probation or parole officer can be a useful ally in working to keep the youth in care. Most correctional facilities provide the medical and mental health records to the child's community pediatrician if the child and parents consent. If the child is released on psychotropic medication, the pediatrician may play an important role in helping the child remain on medication until psychiatric evaluation.

## ADVOCATING FOR THE HEALTH CARE OF CHILDREN IN THE JUVENILE JUSTICE SYSTEM

The AAP Committee on Adolescence published a comprehensive policy statement in 2011 that advocates for involvement of the child's community pediatrician

during and after incarceration so that medical and behavioral health is optimized. Therefore, the institution should refer the youth back to the physician in the community. When the youth does not have an existing community physician, the institutional staff should work with the family (or foster family), parole agents, local public health agencies, and community physicians to develop a plan to coordinate care after release. The institutional staff, in planning for the youth's release, should help the youth and family apply for appropriate health insurance. In some jurisdictions, children in the correctional system remain in the foster care system. If this is the case, the youth may be eligible for Medicaid insurance beyond the usual cutoff age. The AAP policy statement also discusses the need for adequate funding of medical and behavioral health and education in juvenile facilities and suggests that pediatricians should advocate for a reversal of federal law to allow Medicaid and other insurance funding of incarcerated juveniles. Finally, pediatricians working individually and through their organizations should advocate for delinquency intervention programs in the community to decrease the number of incarcerated children.

## CONCLUSION

Pediatricians can help to prevent delinquency by providing parenting support to at-risk families and treatment to young children with disruptive behavior. After a child becomes involved with the juvenile justice system, pediatricians can provide support and counseling for the child's parents as the child traverses the system from arrest to adjudication, sanctions, and rehabilitation. Pediatricians who understand the juvenile justice system in their geographic location are prepared to assist delinquent youths and their families before, during, and after incarceration. Juvenile correctional facilities generally welcome the involvement of the child's community pediatrician if the parents and child consent.

## Chapter 74

# CHILDREN IN SELF-CARE

Robert Needleman, MD

The after-school hours trouble many parents. They may be uncomfortable leaving children to care for themselves or in the care of siblings, but quality after-school programs are often inaccessible or expensive. Pediatricians, aware of the potential stresses and dangers associated with self-care, can help parents find acceptable solutions.

Many, if not most, parents are at work when school lets out (Figure 74-1). According to a 2009 mail survey of nearly 30,000 households selected to mirror the US population, 15% of children aged 5 to 18 participate in after-school programs, while 26% spend time each week in self-care. With increasing age, self-care rises while after-school program participation falls (Figure 74-2). The true prevalence of unsupervised care is difficult to estimate. Parents may under-report children in self-care to avoid stigma or feared legal action; they may even be reluctant to disclose self-care arrangements to their child's doctor.

Self-care represents a spectrum of arrangements. For example, a parent may phone home every hour, may be reachable by phone at any time, reachable only in emergencies, or not reachable at all. The nearest responsible neighbor may be across the hall or a mile away. A child may be home alone, or in the care of an older sibling, or caring for a younger one. Many children spend the after-school hours at the library, which may provide a formal after-school program, informal guidance by a concerned librarian, or merely grudging toleration. Some children go to friends' homes, where there may or may not be a responsible adult. Others meet at the mall, in parks, or elsewhere in the community. It is typical for a child to experience different arrangements on different days of the week, and for arrangements to change from year to year, if not more frequently. Similarly, after-school programs vary in content and quality. This variability needs to be taken into account when counseling parents and when interpreting the research literature.

## EFFECTS OF SELF-CARE: SCHOOL-AGED CHILDREN

Many parents and professionals believe that self-care is harmful. James Garbarino, a well-known researcher and author, has suggested that children in self-care struggle in 4 ways: they feel bad (emotional effects), act badly (high-risk behaviors), develop badly (academic deficits), and are treated badly (risk of victimization).

**Figure 74-1** After-school care, by grade. All numbers are based on findings from the 2014 *America After 3PM* survey. (Reprinted with permission from Afterschool Alliance [2014]. <http://afterschoolalliance.org>.)

**Figure 74-2** After-school care, both parents in work-force, by location. All numbers are based on findings from the 2014 *America After 3PM* survey. (Reprinted with permission from Afterschool Alliance [2014]. <http://afterschoolalliance.org>.)

The research literature, however, is equivocal. For example, studies are divided on the question of whether children are frightened when they stay at home alone. Not surprisingly, children who live in the relatively safe suburbs are less prone to fearfulness than children from violent urban neighborhoods. Increased time in self-care has been associated with poorer classroom adjustment, but not consistently with poorer grades. Children's self-esteem, locus of control, peer relationships, and classroom conduct are similar in self-care and parent care, although some parents report that self-care builds self-confidence.

The diversity of findings likely reflects differences among the populations studied, the definitions of self-care, and the selection of outcome measures. Most of

the studies are cross-sectional, limiting conclusions about causality. Multiple factors go into determining whether a child might be exposed to aftercare and, if so, what type. The salient factors are likely to be hard to quantify, such as a parent's sense that his child is mature enough to handle self-care, or the strength of a parent's guilt or fear about leaving her child unsupervised. There are no randomized studies to provide definitive answers. For children with special health care needs, issues of mobility, communication, judgment, and potential need for administration of medication are likely to be salient, but little if any published information is available to guide the pediatrician and parent in weighing these factors.

## EFFECTS OF SELF-CARE: TEENS

One area in which there is a fairly high level of agreement concerns the association of less adult supervision with increased substance use and other risk-taking behaviors among teens. At home after school is a common time and place for unsupervised youths to take drugs and have sex. Adolescents unsupervised at friends' homes are more at risk of succumbing to negative peer pressure than those who stay in their own homes. Those who hang out with friends without a set location are at greatest risk. Nonpermissive parenting style, family rules prohibiting substance use, and increased supervision (eg, through required telephone calls) lower, but do not eliminate, the risk associated with self-care.

Early adolescents may be particularly vulnerable to the stresses and temptations of self-care. Compared with parent-supervised eighth graders, those in self-care for 11 or more hours per week reported 1.5 to 2 times higher levels of risk taking, anger, family conflict, peer influence, attendance at parties, and substance use. Moreover, earlier initiation of self-care was associated with increased rates of these negative behaviors. For example, 11% of eighth graders in parental care reported heavy alcohol use, compared with 19.5% in self-care since junior high school, and 25.5% in self-care since elementary school. While some adolescents report feeling increased self-reliance and responsibility, others experience loneliness and sadness.

## AFTER-SCHOOL PROGRAMS

Alternatives to self-care include care provided by relatives or hired sitters or structured after-school programs. The Afterschool Alliance ([www.afterschoolalliance.org](http://www.afterschoolalliance.org)), an advocacy group, has compiled numerous studies linking participation in after-school programs with higher academic achievement and less deviant and risky behavior. One critical review of the data, however, was less enthusiastic. Programs aimed at obesity prevention are increasingly common, and the evidence for beneficial effects on activity level, fitness, and lipids is growing. Benefits may extend also beyond the children. High-quality after-school programming may make it easier for parents to remain in the workforce. Conversely, parents often cite inadequate after-school arrangements as a significant source of stress.

The number of after-school programs has grown rapidly in the past decade. For example, the US

Department of Education's 21st Century Community Learning Centers funds after-school academic enrichment programs in low-income neighborhoods across the country. However, while participation in after-school programs is higher among ethnic minority children than in the population as a whole, the need for additional programs in low-income areas is also greater. For example, 61% of African American parents report that they would enroll their children if they had access to programs, compared with 38% of parents overall. Safety, transportation, and access to information about programs are also barriers for underserved groups. Children and youth with special health care needs (CYSHCN) may have special difficulty accessing after-school programs, which may not be equipped to accommodate their medical, developmental, or behavioral needs. Information on program accessibility is not readily available, nor is it tracked nationally. Nonetheless, CYSHCN do participate in a wide range of community activities, dictated more by their personal characteristics than by their category of special need.

As with self-care arrangements, there is great diversity among after-school programs. Cost and quality vary widely. Among indices of program quality, warm interpersonal relationships between staff members and child participants appear to be especially important, supporting both academic and personal-social outcomes. The goal for all children is not merely attendance at after-school programs, but fully engaged participation.

## DECISIONS ABOUT AFTER-SCHOOL CARE

Parents' decisions about after-school care can be relatively straightforward, or can be difficult and fraught with guilt and worry. Self-care can be a positive experience, assuming the child is mature enough, the neighborhood safe enough, and the hours short enough. Box 74-1 presents a common-sense checklist to help parents decide if self-care is right for their children. Many states have adopted guidelines that attempt to help draw the line between acceptable unsupervised care and neglect, although the wording of these documents is sometimes vague; actual laws on the subject exist in only a few states. In many communities, service agencies offer "survival training" to prepare children to cope with self-care. The efficacy of such classes has been questioned, however.

## THE PEDIATRICIAN'S ROLE

Parents are hungry for information about after-school care. Among parents using a family help desk at an urban clinic, the most frequent need (29% of visits) was information about after-school programs. Pediatricians can ask about child care arrangements at health supervision visits for children of all ages. These discussions may be particularly important with respect to children with special health care needs. Parents of school-aged and adolescent children may have questions about care outside of school hours, but may hesitate to bring up the subject. Parents need to understand that the effect of self-care varies depending

### BOX 74-1 Signs of Readiness for Self-care

- **Age:** A sensible 8-year-old should be fine for a half hour or so once in a while, but most children will not be mature enough to manage being alone on a regular basis until they are 10 or 11 years of age.
- **Interests:** The child is able to keep busy reading, drawing, making music, doing homework, and playing with toys among other things (not just watching television or playing video games).
- **Memory:** The child remembers common-sense safety rules, such as not opening the door and not telling telephone callers that he is alone.
- **Common sense:** The child can relate how to respond to a fire, gas leak, or other emergency.
- **Caution:** The child generally shows caution, thinking before acting. This is particularly important for young teens, who are tempted to engage in sexual and other experimentation.
- **Comfort:** The child seems to be truly OK with the idea of being home alone.

on the child and the specific circumstances. Pediatricians can help parents think through the issues as they apply to their individual situation. Awareness of the increased rates of substance use and other risk taking among unsupervised adolescents may lead parents to reconsider self-care for their teenage children. To date, the efficacy of pediatric guidance about out-of-school care has not been demonstrated empirically.

Pediatricians can also help connect parents with community resources such as high-quality after-school programs, latchkey training programs, and telephone "warm lines" that provide safe human contact and support to children alone after school. Locally, service agencies such as the YMCA and Boys and Girls Clubs are likely to be good resources, as are public libraries. Guidance and referrals can be found through the Child Care Resource and Referral Programs in most states, easily located through a national toll-free number (1-800-424-2246). The National Child Care Information Center ([www.icfi.com/insights/projects/families-and-communities/national-child-care-information-center](http://www.icfi.com/insights/projects/families-and-communities/national-child-care-information-center)), has a computerized listing; however, it may be difficult to find online. Where local services are inadequate, pediatricians can play an important role in advocating for more high-quality out-of-school programs for school-aged children and adolescents. Finally, pediatricians can advise parents to learn about the Federal Child and Dependent Care tax credit, which applies to all children younger than 13 years of age and to older children who have special health care needs, and which can substantially lower the cost of after-school care.

## Chapter 75

# GAY- AND LESBIAN-PARENTED FAMILIES

Cindy Schorzman, MD; Melanie A. Gold, DO

Family structures in the United States, as in much of the world, are changing. The traditional structure of a working father and a homemaker mother with 1 or more children no longer describes most of the families in the United States. Alternate family structures are diverse. Unmarried couples may live together with or without children. Single mothers and fathers, stepparents, and blended families may be created by design, by divorce, or by death. These family structures may include gay men and lesbian women, with or without children.

Recent estimates of children in the United States with at least 1 gay or lesbian parent range from 1 to 10 million. According to US Census data from 2000, same-gender couples live in more than 99% of US counties, and nearly 25% of all same-gender couples are raising children. These estimates are limited by barriers to obtaining accurate numbers, in part, because many gay and lesbian parents fear discrimination and do not report their sexual orientation.

Specific research on issues regarding gay and lesbian parenting has been driven by legal issues, chiefly concerning custody. This research has focused on assessing the development and well-being of children raised by gay or lesbian parents. (Box 75-1 contains a glossary of terms.)

## CHILD DEVELOPMENT IN THE CONTEXT OF GAY- AND LESBIAN-PARENTED FAMILIES

No consistent differences exist in the psychological profiles of children raised by gay and lesbian parents compared with children raised by heterosexual parents.

## BOX 75-1 Glossary of Terms

- **Gender identity:** Personal sense of one's integral maleness or femaleness
- **Gender roles:** Behaviors within a culture commonly thought to be associated with maleness or femaleness
- **Homophobia:** Unprovoked fear, distrust, or hatred of lesbian, gay, or bisexual persons
- **Sex:** Classification as either male or female based on external anatomy such as the penis and testes or vulva
- **Sexual orientation:** Persistent pattern of emotional or physical attraction to members of the same or opposite sex. Included are homosexuality (same-sex attractions), bisexuality (attractions to members of both sexes), and heterosexuality (opposite-sex attractions)

During the 1990s, research became increasingly available on children conceived in the context of gay and lesbian relationships.

Children who have gay or lesbian parents do not differ from children who have heterosexual parents in terms of psychological health, social relationships, or cognitive or emotional functioning. The best predictors of child behavior problems are higher levels of parental stress and interparental conflict.

The sexual orientation of parents has not been found to affect the gender identity of their children. Furthermore, adolescent sexual orientation is similar among adolescents raised by gay or lesbian parents and those raised by heterosexual parents. Children raised by lesbian mothers are more likely to explore same-gender sexual relationships, particularly if their childhood family environment is characterized by an openness and acceptance of lesbian and gay relationships. However, these children are no more likely than the children of heterosexual mothers to identify themselves as gay or lesbian.

Pediatricians should be aware that the psychological experience might differ for children raised in heterosexual versus homosexual parenting environments. The greatest difference reported is bullying. Although no overall increase in stigmatization may exist, children of nonheterosexual couples are more likely than those of heterosexual couples to be teased and to be concerned about being harassed. Some children experience shame because of conflicts between loyalty to their parent and the perceived need to conceal their parents' sexual orientation for self-preservation.

The conclusion that research to date demonstrates few discernible differences in parenting based on parental sexual orientation is not universally accepted. Outspoken critics of the literature have highlighted the limitations of these studies, including small sample size (these studies may be more likely to conclude that no differences exist when some differences do indeed exist), lack of generalizability (participants were mostly lesbian, white, well-educated, and upper-middle class), lack of randomization of study populations, and lack of appropriate comparison groups.

However, no studies have been published in the peer-reviewed literature that demonstrate differences

in a child's development based on the sexual orientation of the parents or show any evidence that gay and lesbian parenting causes significant deleterious effects on children. Taken together, the overwhelming number of studies (despite their limitations) demonstrate no differences in children's development based on the sexual orientation of their parent or parents.

The American Academy of Pediatrics (AAP) Committee on Psychosocial Aspects of Child and Family Health reviewed the available data on children of gay and lesbian parents and published a technical report in 2002 with a policy statement supporting co-parent or second-parent adoption by same-gender parents. Their conclusion was that "a growing body of scientific literature demonstrates that children who grow up with 1 or 2 gay and/or lesbian parents fare as well in emotional, cognitive, social, and sexual functioning as do children whose parents are heterosexual," and that "children's optimal development seems to be influenced more by the nature of the relationships and interactions within the family unit than by the particular structural form it takes." Despite some reservations based on the limitations of the studies, such as those noted previously, the Committee thought that the weight of the available evidence was strong enough to demonstrate "that there is no systematic difference between gay and nongay parents in emotional health, parenting skills, and attitudes toward parenting."

## SOCIAL RELATIONSHIPS AND DISCLOSURE

All children, especially as they reach school age, must develop a wide range of relationships outside their nuclear family. Children who have gay or lesbian parents may be assumed to be homosexual and experience stigmatization by peers when their parents' sexual orientations become known. The difference between dominant cultural values in the community and the family constellation may be distressing to children and add to their social isolation and uncomfortable relationships with peers. Gay and lesbian parents often fear that school staff will treat their children differently if they disclose their sexual orientation. As a result, many parents help children learn *differential disclosure*—to be open about their parents' sexual orientation to some people but not to others—so that harassment and social isolation can be minimized. Parents should understand that both secrecy and disclosure represent potential burdens for their children. Further, many families parented by gay and lesbian parents, including those families created by adoption, may be transracial in nature. Physicians should note that this can further contribute to the stressors experienced by the child and the family.

Physicians can act as supportive listeners for families with difficult interactions with their school system. Some physicians with long-standing school relationships may choose to act as intermediaries between the family and the school to help make the educational environment more supportive. They can educate child care providers and teachers and encourage schools to include information about diverse family structures in their libraries and curricula. Physicians can also

encourage families to develop a social support network in the interest of their children. In many larger cities, an active network of gay and lesbian parents works to create an environment of peer support in which their children feel more accepted than they might in other social contexts. Parent-child discussion or playgroups, story hours, and periodic communal meals have helped some parents and children seeking mutual support.

## LEGAL ISSUES

Controversy regarding securing legal parental rights for gay and lesbian parents is ongoing. Legislation constantly shifts the parameters of parental rights and responsibilities. For example, laws in the state of Florida changed in September 2010; Florida's Third District Court of Appeals ruled that the previously established statute, which explicitly stated that homosexuals are not eligible to adopt, violated the state constitution. This resulted in single lesbian, gay, and bisexual individuals being able to petition to adopt in that state; however, same-sex couples in Florida are not able to jointly petition to adopt. It is unclear whether a same-sex partner may petition to adopt his or her partner's adopted child. The spectrum of parental rights for lesbian, gay, and bisexual parents ranges from the 29 states and the District of Columbia that have granted adoptions (either individual/single, joint, or second parent) to gay and lesbian individuals as well as same-sex couples, to states such as Mississippi and Utah, where same-sex couples are prohibited from adopting. Many states have no formal statutory policy on adoption by a gay or lesbian person, and this ambiguity often leaves decisions in the hands of individual judges.

Because courts have continuing legal authority to protect children until they reach 18 years of age, most questions of custody can be reopened in any state in which the child resides. A court can determine what custodial arrangement it finds to be in the child's best interest and can remove the child from the home when parental custody is challenged (eg, by a former spouse or grandparents), particularly when a gay or lesbian parent's sexual orientation was unknown in a previous custody decision. Furthermore, even with court precedents declaring that parents cannot be deprived of child custody based solely on parental sexual orientation, a heterosexual parent is still more likely than a gay or lesbian parent to be granted custody and visitation rights unless the heterosexual parent is unavailable or obviously unfit.

In the frequent circumstance that only one person from the same-gender couple is legally recognized as a child's parent, the physician should clarify how responsibility for the medical decisions and consent for treatment for the child will be shared and document this in the medical record. In the event of serious injury, illness, death, or voluntary separation of the legal parent, a prior written agreement giving the other parent power of attorney in making medical decisions for the child is necessary.

In general, when gay or lesbian couples first contemplate raising a child together, they should agree in writing on issues concerning child custody, support, and consent for treatment. Curry, Clifford, and Hertz

give guidelines for writing agreements that specify parental rights and responsibilities. Without a written agreement, nonbiologic or nonadoptive parents may have difficulty proving their status as parents.

## CLINICAL ISSUES IN PROVIDING PEDIATRIC CARE

The challenge for the pediatrician who cares for these children lies in addressing practical concerns faced by individual families. Meeting the needs of children of gay and lesbian parents means addressing the needs of the children themselves, as well as understanding the particular issues within the context of their family as a whole. Gay or lesbian parents may choose not to identify their sexual orientation to their child's pediatrician. They may worry that latent homophobia or bias among professional or nonprofessional staff will jeopardize the care their children receive or that the pediatrician will not honor their confidentiality, particularly if the parents are concerned about legal threats to their custody rights. The challenge for the pediatrician caring for these children often lies in creating an environment in which members of the family feel comfortable enough to disclose and discuss the parents' sexual orientation and the family constellation. Health care professionals have traditionally received little or no training about homosexuality. In fact, evidence suggests that gay and lesbian adults find the health care system to be unresponsive and sometimes antagonistic to their unique needs and concerns.

Little information exists about how lesbian and gay parents view pediatric care. One study found that most gay and lesbian parents perceived that their children received pediatric care that was affirming, supportive, and satisfactory. However, many specific deficiencies were noted, such as heterosexist assumptions on office forms, exclusion of the nonbiologic parent from the evaluation and treatment process, and explicit insensitivity to particular family involvements. In addition, parents who had not disclosed their sexual orientation to their child's pediatricians had concerns that such disclosure might compromise their child's care, result in negative judgments about their parenting, and infringe on their confidentiality. They described a significant number of concerns regarding physicians, such as prejudice against their children, providing disparate care, lack of communication about the child's health with the nonbiologic parent, and identifying parental lifestyle as the cause of any child physical or behavioral problems.

Pediatricians can create a safe and inclusive environment for same-gender parents and their children. Establishing a supportive health care environment requires that pediatricians first examine their own attitudes toward gay and lesbian parenting. Perrin and Kulkin assert that physicians "who cannot reconcile their personal beliefs with their professional obligation to provide supportive, understanding, and respectful care to gay and lesbian families should recognize this limitation and refer these families to a pediatrician who can better meet their needs." Once the pediatrician has addressed these issues personally, then health care staff attitudes can be similarly

addressed with interventions such as diversity training and strict guidelines regarding confidentiality.

Pediatricians can convey their support of all forms of families, and the office environment can reflect a supportive, safe environment for children of diverse families. Hospital and office policies regarding the use of gender-neutral language and the inclusion of nonbiologic parents during the child's office visits can be discussed and enforced. Box 75-2 illustrates examples of questions to clarify family constellation in ways that can be applied to any family system, including blended and adoptive families. In their work, Perrin and Kulkin identified several changes in the office or hospital environment that demonstrate support for diversity of family structures. These efforts include displaying posters, magazines, books, and pamphlets that portray a wide range of family constructs. A nondiscrimination policy, prominently displayed in the waiting area, can do much to assure members of a diverse array of family structures, including, but not limited to, gay and lesbian parents and their adolescent children, that the office is a safe environment for disclosure of sensitive issues (Figure 75-1). Standard office forms can be modified to include gender-neutral terms, such as *parent*, *caregiver*, and *family member*. Resources can be made available in the office, such as books about gay and lesbian parenting, information regarding community and national support groups, and standard medical forms such as medical power of attorney designation.

As the child grows and develops, in addition to standard anticipatory guidance issues, particular concerns tend to surface at different developmental stages. In the preschool period, common concerns include how to explain the composition of their own family and the methods of reproduction. Gold and colleagues suggest that early childhood "is a good time to

### BOX 75-2 Questions to Clarify the Family Constellation

- Is there anything about your family that would be helpful for me to know?
- Who are the adults who make up your family?
- Who are the important people in your child's life?
- Who lives at home? What is your relationship with each child caretaker?
- By what name does your child call each family member?
- Who are the other important members of your family or support system who help care for your child?
- Do you share parenting responsibilities with anyone else?
- Who helps you with parenting?
- Is there anyone else who participates in parenting?
- Do(es) the biologic parent(s), if not part of the current constellation, have any involvement in child care?
- Which of your child's caretakers can give legal consent for medical care?
- Do any of your child's biologic relatives have any medical conditions?

### Office Nondiscrimination Policy

This office appreciates diversity and does not discriminate based on race, national origin, age, religion, ability, sexual orientation, or perceived gender.

**Figure 75-1** Example of nondiscrimination policy for the pediatric office.

initiate explanations to the child about his own origin and to introduce concepts of the variety of loving relationships.” Pediatricians can help parents empower their children to deal with these issues by encouraging them to allow the child to control the information she discloses to friends or teachers; parents should simultaneously help their children prepare for the possible negative consequences of disclosure.

Parents should be encouraged to help their children come up with their own creative ways to describe their family in positive terms. A gay or lesbian couple might celebrate their essential roles as 2 loving supportive parents while additionally recognizing the other important adult role models and caretakers who comprise the child’s extended family. For example, in the context of a lesbian couple with children, one approach to Father’s Day might be to redefine it as a celebration of the child’s male role models, such as writing cards to an uncle or close male family friend.

The transition to school years also poses particular challenges for children from a nontraditional family background. For parents and children alike, this transition involves deciding whether to disclose their nontraditional family status to teachers and the families of the child’s friends. During the early school years, peer acceptance and teasing often become concerns. In the National Lesbian Families Study, 18% of children had experienced some form of discrimination by age 5, and 43% had experienced homophobia by age 10. Empathic listening, role playing about how to respond to teasing, and providing information to parents and their children through support groups can assist both parents and children in coping with stigma and discrimination.

During adolescence, issues of sexuality tend to come to the forefront regardless of family structure; teenagers in households with lesbian and gay parents are certainly no exception, and they may have their own unique challenges. Early adolescents may feel marginalized and stigmatized by being seen as part of a nontraditional family. Teenagers may feel guilty, torn between their loyalty to their family and pride in their family structure, and their intense desire to form and maintain relationships and fit in with their peers. Physicians can help adolescents and their parents by listening in a nonjudgmental fashion and by offering lists of resources and support groups. Although individual situations vary, some evidence supports encouraging adolescents to disclose their nontraditional family status to their friends. Gershon

and colleagues found that adolescents who disclosed their mother’s lesbianism to their friends reported closer friendships and higher self-esteem than those who did not.

To meet the ever-changing needs of patients and their families, pediatricians should have available a list of local and national support groups and community resources (see Tools for Practice). They might also consider taking a proactive approach in their patients’ lives by not only providing a safe, nurturing office environment, but also taking steps in the community to help counteract the generalized homophobia that children of gay and lesbian parents continually face.

## PHYSICIAN ADVOCACY

Although no evidence has been found that children raised by gay or lesbian parents will develop abnormally or be less well adjusted than other children, these children may be faced with criticism and isolation, which may affect their self-esteem. Pediatricians have an opportunity to help change social attitudes and restrictive legal codes that are damaging to their patients with gay and lesbian parents. Pediatricians who care for these children should be informed about community resources and may choose to be available as consultants to schools and to gay and lesbian support groups. They can learn which community and national programs are supportive of gay and lesbian parents. Pediatricians may choose to be available as consultants to schools and to gay and lesbian support groups and to provide guidance to gay and lesbian parents regarding child care and school selection. Pediatricians can also provide a bibliography of books for children and parents (see Box 75-3) and a list of local and national resource groups (see Box 75-4). Above all, pediatricians have the opportunity and the responsibility to support and advise all families in achieving their maximal nurturing potential.

## CONCLUSION

Children will flourish in various family environments as long as these settings include adequate nurturance and guidance for optimal development. Although no data have been found to suggest that children with gay or lesbian parents are different from other children with regard to their cognitive, psychosocial, and sexual development, these children and their families face social challenges that pediatricians can help address. These challenges are best met within the context of the child’s life as a whole, and the routine medical care of children and adolescents should not be overshadowed by their nontraditional family status. The diversity of the family structures of the gay and lesbian community should be recognized, and anticipatory guidance and care should be tailored to individual needs.

## Chapter 76

## LESBIAN, GAY, AND BISEXUAL YOUTH

Robert J. Bidwell, MD

In 2004, the American Academy of Pediatrics (AAP) issued its clinical report on sexual orientation and adolescents. This report was followed, in 2013, by an AAP policy statement titled “Office-Based Care for Lesbian, Gay, Bisexual, Transgender, and Questioning Youth,” which broadened the scope of interest to youth dealing with issues of both sexual orientation and gender identity. Together, these affirm the physician’s responsibility to provide supportive and comprehensive health care to all youth, including those who are lesbian, gay, bisexual, transgender, and questioning (LGBTQ). They also provide physicians with the understanding and tools to do so in a respectful and relevant manner. Because LGBTQ adolescents are present in every pediatric setting, an understanding of sexual orientation and gender identity and the unique experiences and needs of LGBTQ youth is essential to the practice of pediatrics.

## DEFINITIONS

*Sexual orientation* is an integral part of human sexuality; it refers to an individual’s pattern of affectional, romantic, or sexual attractions to the same sex (homosexual), opposite sex (heterosexual), or both sexes (bisexual). Homosexual men are generally referred to as *gay*, homosexual women as *lesbian* (or *gay*), heterosexual individuals as *straight*, and bisexual individuals sometimes as *bi*. Sexual orientation is generally represented as a continuum from completely homosexual to completely heterosexual, with many individuals finding themselves somewhere in between. Some individuals describe themselves as asexual, attracted to neither sex. Some youth are not yet certain of their sexual orientation or gender identity and are referred to as *questioning*. Others may engage in same-gender sexual behavior, but not describe themselves as lesbian, gay, or bisexual. They are sometimes referred to as *men who have sex with men (MSM)* or *women who have sex with women (WSW)*. *Gender identity* is another important aspect of human sexuality, distinct from sexual orientation; it refers to a person’s inner sense of being female, male, or another gender. Although too simplistic a definition, *transgender* individuals are generally described as those whose genetic and anatomic sex may be female or male, but whose inner identity is of another gender. *Transgender* may also be used as an umbrella term encompassing the many forms of gender identity and gender expression that are anything other than *cisgender* (when birth gender and experienced or expressed gender are the same). Although the experiences and needs of transgender youths are not discussed in this chapter, a growing number of clinical guidelines address these issues (see Chapter 156, Gender Expression and Identity Issues). Although the term *queer* has historically

been considered pejorative, an increasing number of LGBTQ and other individuals across the broad spectrum of gender and sexuality are claiming this term, along with *genderqueer*, as positive descriptors of their identity.

## PREVALENCE

The percentage of adolescents who recognize or eventually will recognize their lesbian, gay, and bisexual (LGB) identities is uncertain. Estimates for gay and lesbian individuals within adult populations range from approximately 3% to 10%, with an even larger percentage being bisexual. Whatever the exact percentage, LGB adolescents are present in all pediatric practices. They exist within all ethnic, religious, and socioeconomic groups and may be more highly represented among homeless and runaway youths and those in the juvenile justice and child welfare systems. However, LGB adolescents are often unrecognized, either because they do not fit LGB stereotypes, because they have not yet labeled their orientation as LGB, or because they are reluctant to reveal in health care settings their sexual orientation for fear of primary care physician (PCP) disapproval or lack of confidentiality. Many of these individuals likely remain unrecognized because PCPs do not routinely address sexual orientation with their adolescent patients.

## DEVELOPMENT

The process of LGB identity acquisition is long, complex, and often difficult because of the generally negative societal stance toward nonheterosexual orientations. Several models of LGB identity formation have been proposed, each citing stigma as a major factor influencing development. Troiden and Cass offered early models of identity acquisition, proposing stages of increasing self-acceptance as an individual moves from childhood through adolescence into adulthood. Later research suggests these models were perhaps too linear, requiring an individual to pass through one stage to the next on the path to full self-acceptance. More recent models suggest much more complex and varied developmental paths. They take into account the many factors involved in sexual identity development which, in addition to biology, include ethnicity, gender, social class, geography, degree of family and community acceptance, life experiences, and personality traits. The PCP should, therefore, not assume a predefined developmental trajectory for any given patient.

As reflected in the 2004 AAP clinical report and 2013 AAP policy statement, the pediatric profession views heterosexuality, homosexuality, and bisexuality as equally valid and healthy developmental outcomes for youth. This view is consistent with the American Psychiatric Association position that homosexuality is part of the spectrum of normal human sexuality. Homosexuality and bisexuality seem to be well established by early childhood and are not a choice or a matter of something gone wrong. Sexual orientation is likely shaped by biologic, genetic, and environmental factors, and these influences may differ for different individuals. Biologic theories seem to have received the strongest research support in recent

years. Despite supportive AAP statements and a growing understanding of the biologic underpinnings of sexual orientation, significant sectors of American and other societies do not accept the normalcy of homosexuality and bisexuality, seeing them as shameful, sinful, or pathologic. This negative view has significant adverse implications for the development of LGB youths.

## ENVIRONMENTAL EFFECTS

LGB youths are ordinary adolescents in every regard, except that most grow up in environments that are deeply disapproving of their sexual orientation, a fundamental part of who they are. Research strongly suggests that societal stigma and the resultant victimization and discrimination under which LGB youths grow up are the primary reasons for the unique physical, emotional, and social problems they face. While increasing numbers of LGB youth are finding support within their families and communities, many still experience an adolescence of profound isolation, believing they are absolutely alone in their feelings of same-sex attraction. They have little or no access to accurate information about sexual orientation, yet they may be surrounded by a multitude of negative messages about homosexuality coming from their families, schools, churches, and communities and often from people they love and respect. Many LGB youths have little or no access to LGB-supportive PCPs, counselors, or community programs. Some grow up in families and communities where prejudice, discrimination, and violence against LGB individuals are approved or tolerated. Home and school can be especially dangerous places for LGB youths whose sexual orientation is known or presumed. Gender-nonconforming youths seem to be especially vulnerable to victimization and risk for suicidal symptoms.

Given the stigma related to homosexuality and their own fears about their emerging same-sex attractions, many LGB youths repress their same-sex feelings or decide to keep them hidden from others, some expending great energy attempting to pass as heterosexual. They may avoid any exploration of their LGB orientation, thereby delaying an essential part of their identity development. Most LGB youths are denied socially approved dating rituals through which adolescents begin to explore, understand, and become comfortable with their sexuality. Many LGB youths have never had sex with another person; others have been only heterosexually active. Some LGB youths realize that the only way to begin exploring their same-sex attractions is through secretive or anonymous sexual encounters; such encounters are likely increasingly facilitated through the Internet. Although these situations are understandable given the lack of opportunities for sexual socialization enjoyed by heterosexual youths, they are potentially dangerous and may engender feelings of anxiety, guilt, and self-hatred. A small minority of LGB youths are fortunate to live in communities where schools and agencies have begun to provide safe, healthy, and accepting venues, such as school-based gay-straight alliance (GSA) clubs, support groups, drop-in centers, dances, and leadership retreats, for LGB adolescents to meet one another and engage in a process of healthy peer socialization.

LGB youths of color, immigrant youths, disabled youths, rural youths, and youths belonging to conservative religious faiths may have an especially difficult time understanding and accepting their sexual orientation. This intersection of multiple, often stigmatized or conflicting identities is thought to place these LGB youths at even greater risk than their LGB peers. In many instances, they have few LGB-supportive resources within their communities and risk rejection if they openly acknowledge or explore their LGB identity.

Some LGB youths, as with other adolescents who are alone, fearful, and stigmatized, respond in predictable ways, by dropping out of school, running away from home, engaging in risky sex, using drugs, and turning to street life and prostitution. Persons struggling for survival on the streets often encounter violence and sexual exploitation, with the attendant risks of sexually transmitted infections (STIs) and pregnancy. A significant percentage of LGB youths consider suicide to be their only choice. PCPs should realize that these risky behaviors are not a necessary part of the script for growing up LGB. Research has shown that vulnerable adolescents who grow up in stigmatizing or risky environments thrive when they are connected to safe and supportive families, friends, and communities. One of the most important roles for PCPs in working with LGB youths is to participate in creating safe environments and supportive networks of family, peers, teachers, counselors, clergy, PCPs, and others to buffer the often hostile society in which LGB youths grow up. An equally important role of the PCP is to remind LGB youths and their families of the very positive social changes that are occurring. These are evidenced by the expansion of civil rights on many fronts, including same-sex marriage, the increased presence of respected and openly LGB people in media and across many occupations, and the growing acceptance of LGB people across many sectors of American society, including communities of faith.

## EVALUATION

The 2013 AAP policy statement on office-based care of LGBTQ youth, together with its accompanying technical report and *Bright Futures* guidelines for health supervision, provides detailed guidance on providing respectful and relevant care to LGBTQ adolescents. These and other guidelines also describe ways in which physicians can provide care that is respectful of LGB patients and relevant to their needs. PCPs should not presume an adolescent's sexual orientation on the basis of stereotypes or reported sexual behaviors. One of the greatest barriers LGB youths face in receiving appropriate health care is PCPs' belief that they have no LGB adolescents in their practices. Many LGB adolescents will deny same-sex attractions or behaviors even when directly asked. This tendency may be the result of fear of physicians' disapproval or lack of confidentiality or of their own uncertainty about their sexual feelings. Fortunately, the goal of pediatric practice is not to identify all LGB adolescents. Instead, the objective is to create a safe and comfortable clinical setting in which adolescents can discuss sexual orientation issues when they are ready to do so. This task can be accomplished indirectly through posters,

brochures, health questionnaires, and other clinic forms that demonstrate respect for diversity, including diversity of sexual orientation and gender identity. More direct messages come from office staff and PCPs who model respectful attitudes and make no assumptions about sexual orientation or gender identity in their interactions with patients.

Perhaps the strongest message that would allow an LGB adolescent to open up and discuss these issues is when these issues are raised routinely, in a genuinely interested and nonjudgmental manner, at all well-teen visits and any visit suggestive of an adolescent in distress. It is important that the PCP open the door to discussion, because adolescents, uncertain of how their PCP may respond, will seldom raise these issues on their own. A candid discussion of sexuality and other personal issues is facilitated further by meeting with the adolescent alone, without parents or friends present, and accompanied by appropriate assurances of confidentiality. Revealing an adolescent's LGB orientation to others, including parents, without the youth's consent is unethical and potentially dangerous. If issues of LGB orientation arise, then adolescents should be asked whether they are comfortable with the PCP recording these in the chart. Although there are increased recommendations to record sexual orientation and gender identity in the medical record to provide optimal care, adolescents in particular may have concerns about confidentiality that are justifiable and should be respected. Even with permission, these notations should be made carefully and perhaps indirectly, because parents often have the ability to obtain or review their adolescent's medical record, including specific parts that should remain confidential.

PCPs must reflect on their own attitudes and comfort around issues of sexual orientation and consider how their personal biases might affect their ability to provide quality care. Research has shown that many pediatric PCPs are uncomfortable in discussing sexuality, including sexual orientation, with their adolescent patients, and this discomfort limits their ability to provide appropriate care. Studies of LGB adolescents reveal that only a small minority of them have ever been asked about or discussed sexual orientation with their pediatricians. Research has also demonstrated that many PCPs disapprove of homosexuality. This disapproval makes the provision of appropriate health care and counseling to LGB youths nearly impossible. The failure of PCPs to discuss relevant health issues knowledgeably, comfortably, and nonjudgmentally has been a major barrier to accessing health care for LGB youths. Only when issues of sexual orientation are addressed openly and supportively can appropriate medical screening, treatment, education, counseling, and advocacy be provided. Physicians who recognize their discomfort or disapproval around issues of sexual orientation should refer adolescents who may be dealing with these issues to accepting and supportive pediatricians.

### History

Every annual well-teen health evaluation should include a sexual history. Sexual activity, sexual orientation, and sexual decision-making skills should be routinely

assessed at these visits. Sexual orientation also should be addressed with youths having chronic or recurring somatic complaints or at any acute care visit suggestive of an adolescent in distress (eg, parent-teen conflict, school problems, substance use, increased heterosexual or homosexual activity, depression, self-harm, or unusual displays of anger or frustration). Signs and symptoms of STIs should also prompt an inquiry into sexual practices and orientation.

In addressing sexuality with an adolescent patient, the PCP should begin by using gender-neutral language, letting the adolescent know that no assumptions are made about the patient's sexual orientation or practices. For example, the use of terms such as *partner* rather than *boyfriend* or *girlfriend* and *protection* rather than *birth control* is important until a more complete history has been obtained. The PCP can approach the issue of sexuality first by asking if an adolescent has ever been in a dating or romantic relationship with another person. If yes, have these relationships been with girls, boys, or both girls and boys? To learn whether an adolescent has been in a dating or romantic relationship, the physician also should ask, "Have you ever had sex with another person, including just kissing or touching?" If the answer is yes, again, the PCP should ask, "Has this been with girls, boys, or both boys and girls?" An important point to remember is that the question, "Have you ever had sexual intercourse?" may be interpreted as meaning only vaginal intercourse and may not identify youths who have engaged only in petting, oral sex, or anal intercourse.

PCPs should remember that many LGB youths may only have been heterosexually active or not sexually active with others at all. Youths who have been homosexually active may be afraid to acknowledge same-sex behaviors. Therefore, the PCP should search beyond dating relationships and sexual behaviors and ask all adolescents if their feelings of attraction are generally to girls, boys, or both boys and girls, and should also ask about their comfort around these feelings. Many LGB adolescents have not yet labeled their sexual feelings, and, therefore, asking patients early in the interview whether they consider themselves gay, lesbian, or bisexual is usually an ineffective and sometimes frightening screening approach for LGB adolescents. However, as part of a broader discussion over time, asking an adolescent in a supportive and nonjudgmental manner, "Have you ever wondered if you might be lesbian (gay, bisexual)?" may be appropriate at some point. Finally, use of the word *homosexual* as a label ("Are you a homosexual?") is thought to be stigmatizing by many LGB patients and should be avoided.

In interviewing adolescents who acknowledge same-sex behaviors or attractions, the PCP should not focus only or even primarily on their sexual practices and the degree to which they employ safer sex. Because most of the health risks faced by LGB youths are related not to their sexual behavior, but to growing up in a hostile environment, the PCP should address these latter issues in depth before engaging in a detailed discussion of sexual behaviors. For example, the PCP should ask how comfortable LGB adolescents feel about their same-sex attractions and relationships.

How do family background, religion, ethnicity, or community norms play a role in their degree of self-acceptance? The PCP also should ask whether the patient has told others of his or her LGB orientation and whether family members, friends, school counselors, and others have been supportive or rejecting in their responses. In other words, knowing whether an LGB youth is isolated or has a network of supportive family, friends, and adults already in place is important. Another area to explore with LGB adolescents is the degree to which they think their sexual orientation will limit or enhance their future in terms of career, relationships, or acceptance in the community. Can they envision themselves as happy, healthy, and productive LGB adults? What are their concerns or fears, if any? What are their hopes and dreams?

Because some LGB adolescents respond to stigmatization and rejection by engaging in risky behaviors, the PCP should inquire directly about the possibility of parent–teen conflict, school problems, runaway behavior and street life, sexual exploitation, substance use, eating disorders, depression, suicidal ideation or behavior, and involvement in the child welfare or juvenile justice systems. Because many LGB adolescents grow up in nonaccepting or even hostile environments, the PCP should ask specifically about their experience of violence in the home, school, and community. When providing care to LGB youths in the child welfare or juvenile justice systems, PCPs should be aware that although there are standards of care recommending respectful and supportive treatment of LGB youths in foster care and other out-of-home settings, they are not always met. Therefore, PCPs should respect the confidentiality of LGB youths in these systems, recognizing that disclosure of sexual orientation and gender identity through verbal and written communications and documentation could put these youths at greater risk related to safety and the receipt of appropriate care.

As when treating other sexually active adolescents, the PCP should ask sexually active LGB youths how comfortable they are with their sexual behaviors and relationships. Specifically, have these behaviors and relationships been healthy and fulfilling or unpleasant and exploitative in nature? A comprehensive health history should also include a detailed sexual history. It should be preceded by an explanation from the PCP that obtaining personal information about sexuality is helpful in providing patients quality care that meets their specific needs. At the same time, the adolescent patient should be assured that they have a right to answer only specific questions they are comfortable answering. The sexual history should include a discussion of specific sexual behaviors in which the adolescent is engaged, frequency of activity, consensual and nonconsensual encounters, safer-sex practices, number and nature of partners (age, boyfriend or girlfriend vs acquaintance or anonymous), and how contact with potential partners is made (school, church, malls, parties, the Internet). Few sexual practices exist that are unique to LGB youths; thus, history taking related to this specific issue is similar for both LGB and heterosexual youths. Symptoms of STIs also should be elicited, as should any history of combining

substance use and sexual activity or exchanging sex for money, drugs, or shelter.

### Physical Examination

The physical examination of LGB adolescents, whether sexually active or not, does not differ from that of heterosexual adolescents. At the same time, PCPs should remember that many LGB youths are *invisible*, so that any adolescent may have a history of same-sex activity, although it may not always be acknowledged. PCPs should also remember that some gay and lesbian youths have been heterosexually active. The content of the physical examination should be determined by a comprehensive health history, including sexual and other risk behaviors, and not by sexual orientation. If indicated by history, a thorough anal examination should be performed because people of both sexes with a history of receptive anal intercourse are at higher risk for anal STIs, including human papilloma-virus infection, which may lead to anal dysplasia, anal warts, and subsequent anal carcinoma.

Lesbian adolescents should be offered the same gynecologic care as other young women, as guided by a complete and accurate general health and sexual history. Lesbian adolescents who exclusively have sex with other women are not at risk of pregnancy and usually have a lesser risk for STIs than girls who are bisexually or heterosexually active. Although generally not considered STIs, bacterial vaginosis and candidal vulvovaginitis are considered potential STIs between female sexual partners. Many lesbian youth have had male sexual partners, either consensually or through coerced or forced sex, and therefore are at increased risk of pregnancy and STIs. The patient may choose not to share these encounters with the PCP, who must remain open to the possibility of discovering signs of pregnancy and a broad range of STIs on physical examination. Many lesbians, including some adolescents, choose pregnancy as a route to parenthood and will require prenatal care that takes into account their specific life circumstances.

### Laboratory Evaluation

Any decision to offer laboratory or other diagnostic testing to LGB adolescents should be based on a complete and accurate health history (including sexual behaviors) and physical examination and not on sexual orientation. In considering laboratory and other evaluative studies, the PCP should remember that any adolescent may have a history of same-sex encounters and yet be fearful of disclosing them. If a sexually active adolescent is considered at lower risk for STIs (eg, only a single sexual partner and consistent condom use), STI testing may be offered annually. Higher-risk sexual activity, including having multiple sexual partners and the use of drugs or alcohol around the time of sexual activity, warrants more frequent testing. For sexually active gay male youths and MSM, the 2013 AAP technical report on office-based care of LGBTQ youth recommends (1) human immunodeficiency virus (HIV) serology if HIV negative or not tested in the past year; (2) syphilis serology; (3) urethral testing for *Neisseria gonorrhea* and *Chlamydia trachomatis* using a nucleic acid amplification test (NAAT) if the patient has engaged

in insertive anal intercourse in the past year; (4) rectal testing for *N gonorrhea* and *C trachomatis* if the patient has engaged in receptive anal intercourse in the past year; and (5) pharyngeal testing for *N gonorrhea* if the patient has engaged in receptive oral intercourse in the past year. Some recommend herpes simplex virus (HSV) serology testing for all sexually active gay and bisexual male youths and an anal Papanicolaou smear for any adolescent reporting receptive anal intercourse. All sexually active gay and bisexual male youths and MSM should be screened for Hepatitis B (HB<sub>s</sub>Ag). The evaluation and treatment of STIs are discussed in Chapter 330, Sexually Transmitted Infections.

## MANAGEMENT

As stated in the 2004 AAP clinical guidelines, the goal of care in working with LGB youths is “to promote normal adolescent development, social and emotional well-being, and physical health.” PCPs can help realize this goal not only by focusing on the risks that LGB youths face, but also by identifying specific strengths that have allowed them to survive and often thrive in the face of often hostile environments. Historically, because of the serious risks faced by LGB youths, PCPs and allied youth service providers have employed a *risk-reduction model* in addressing the experience and needs of these young people. This model focuses on the vulnerabilities of LGB youth and the need to ameliorate the risks and manage the problems they face. Under this model, healthy adolescent development often seemed to be defined primarily as an avoidance of risk and an absence of negative activities, such as substance use, unsafe sex, dropping out of school, running away from home, or suicidal behavior. Unfortunately, this approach tended to underestimate the strength and resiliency of LGB youths, many of whom presented to their PCPs after having overcome enormous obstacles, including parental rejection, bullying, and internalized homophobia. In working with LGB adolescents, PCPs should adopt an approach that recognizes and builds on the developmental potential of most LGB youths to overcome the risks and obstacles they encounter. This approach is reflected in the *Youth Empowerment* and *Positive Youth Development* models of supporting healthy adolescent development. These approaches seek to support youths in recognizing their strengths and gaining the self-confidence and skills needed to address challenges and create change in their own lives and in the world around them. PCPs can employ this approach in their counseling and encouragement of individual patients. They can also join with others in providing opportunities for LGB youth to assume a leading role in sharing the stories of their lives with others, in creating LGB youth support activities, in achieving leadership skills, and in engaging in civic affairs that address their specific experience and needs. This approach is directly related to risk reduction, but also transcends this narrow goal by providing opportunities for LGB youths not just to survive, but to achieve their full developmental potential and thrive.

### Physical Well-being

LGB adolescents face the same kinds of health issues as other adolescents. Therefore, PCPs should follow

AAP policy and *Bright Futures* guidelines in providing prevention and screening services to LGB youth. The health screening, immunizations, and treatment provided to LGB adolescents should not be based on sexual orientation, but rather on information obtained from an accurate history, physical examination, and evaluative studies. Nevertheless, many LGB youths face increased risks to health because of societal non-acceptance. Patients who show evidence of drug dependency, eating disorders, depression, anxiety, and other mental health concerns should be referred to appropriate LGB-supportive community resources. As an LGB adolescent approaches adulthood, discussions about transition to an LGB-supportive adult health care provider should begin.

### Developmental, Social, and Emotional Well-being

Although providing appropriate health care is important, for many LGB adolescents, the most important role a PCP can play is that of supportive counselor. Adolescents who acknowledge same-sex or bisexual attractions exhibit varying levels of self-acceptance and differing issues of concern. Therefore, a first step in counseling LGB adolescents is to listen carefully to their stories, because these will help shape the content of issues to be discussed during the present and subsequent visits. In general, the counseling of LGB adolescents addresses the following 6 areas: self-acceptance and validation of same-sex attractions; safety; connectedness to supportive others; self-disclosure, or *coming out*; healthy relationships and sexual decision making; and optimism for the future. PCPs often focus their counseling of LGB adolescents only on sexual activity, risk for STIs, and safer-sex practices. However, addressing each of the 6 areas listed here is important in ensuring the healthy development of LGB adolescents.

### Self-acceptance and Validation

Most adolescents grow up surrounded by negative messages about LGB sexual orientation and the presumption that heterosexuality is the only acceptable orientation. These messages often come from people they love and respect and have a profoundly negative effect on the health and development of LGB youths. LGB adolescents often think they are sick or sinful because of their emerging sexual feelings and are filled with shame and self-hatred. The PCP should try to determine the degree of comfort each LGB youth has with emerging sexual feelings and discuss the adolescent's specific concerns or fears. While acknowledging that some cultures and communities may view LGB orientation as unhealthy or wrong, the PCP should state clearly that the pediatric profession considers homosexuality and bisexuality to be healthy and normal. They are not a choice and do not represent something gone wrong. This emphatic reassurance of normalcy from the pediatric perspective is perhaps the most powerful and important statement that a PCP can make to a LGB youth. The PCP should also determine an adolescent's accuracy of knowledge about sexual orientation and correct any misconceptions. Some LGB youths are frightened by LGB stereotypes,

thinking these somehow represent who they are as a person. The PCP should remind LGB adolescents that the stereotypes do not define who they are; rather, they, in their own individuality, help define what it means to be LGB. Ethnic and other minority LGB youths may have an especially difficult time as they try to manage more than 1 type of stigma. The PCP should recognize and discuss this difficult reality with the patient. Letting the LGB adolescent know that growing self-acceptance of a person's sexual orientation is an evolutionary process is helpful. The uncertainty and discomfort they experience now will likely diminish or disappear as they move into adulthood.

If an adolescent denies same-sex attractions, and yet the PCP or others think that it is an issue that may emerge later in an adolescent's life, then the PCP can simply say, "This may or may not ever be a part of your life, and I hear you telling me clearly today that it is not. I just want you to know that, as your doctor, I will always be here for you and available to discuss any issues that come up in your life as you grow older."

For adolescents who express uncertainty about their sexual orientation, the PCP can say, "It's not my place to tell you if you are gay, lesbian, bisexual, or straight; only you can decide this for yourself. What I can do is provide you information and support, and let you know that whoever you finally discover you are is all right. The most important thing is that you are happy and comfortable with who you are, no matter what your sexual orientation might be." It is not unusual for some adolescents to go through stages during which they think they are gay, then straight, then bisexual, then gay again. This uncertainty is part of the normal process of self-discovery and will eventually be resolved, although not necessarily during adolescence. The PCP should not tell adolescents who are experiencing same-sex attractions that they are "just going through a phase." For a significant percentage of adolescents, these feelings do, in fact, represent an emerging LGB identity, and false reassurances to the contrary can be harmful. PCPs should be ready to link adolescents who are LGB or questioning with supportive national organizations that maintain Web sites providing accurate and validating information and resources for teens. Other organizations provide tools for physicians to help them engage LGB adolescents and their families (see Tools for Practice).

## SAFETY

Many LGB youths grow up in environments that are potentially harmful to their physical, emotional, and developmental health. Many of these individuals endure harassment and bullying, discrimination, or social rejection; at the very least, many are surrounded by negative messages about LGB orientation. These dangers may arise at home, school, or church, and within the peer group or the broader community. PCPs should ask LGB adolescents about their safety in each of these settings. If an adolescent acknowledges teasing, harassment, or other harmful treatment, then the PCP should work with the youth to identify and implement appropriate strategies to end the violence. Unfortunately, many LGB adolescents

are filled with shame and are afraid to advocate for their own safety. They may feel that reporting harassment will only make the situation worse. They often think that they deserve the harm inflicted on them, or they simply accept the situation as normal. The PCP should tell adolescents clearly that they have done nothing to deserve such treatment and that they should expect and demand safety and respect from everyone in their lives and in all settings. Because LGB youths have so few advocates, the PCP should offer to join with the adolescent in approaching every venue in which the adolescent experiences violence, including the home and school, to work out a plan to end violence immediately and completely. If necessary, the PCP should call on the state child protective services or advocacy organizations such as the American Civil Liberties Union to join in the effort to keep the adolescent safe.

## ISOLATION

LGB adolescents are among the most isolated of youths. Although there have been significant societal changes in attitude toward homosexuality, many LGB adolescents continue to have little or no access to accurate and supportive information about sexual orientation, and many know of no accepting and supportive counselors in their schools or communities. At a time when they should begin exploring their sexuality, most LGB adolescents have no safe venues in which to meet other LGB youths. Many of them have distanced themselves emotionally or become estranged from their parents and siblings. Many LGB adolescents believe they are the only ones they know who are experiencing same-sex attractions. Few of them have visible LGB adult role models in their communities to provide reassurance that a happy and rewarding adulthood is attainable. As with any other adolescents, isolation and loneliness can lead to compromised physical and emotional health, including increased risk for anxiety and depression. PCPs should routinely screen for these possibilities (see Tools for Practice) and address the issue of isolation by giving accurate information about sexual orientation. They should provide supportive and reassuring counseling, or they should refer the adolescent to LGB-supportive colleagues who have the time, comfort, and expertise to do so. They should connect LGB youths to local community resources, such as support groups and other youth programs for LGB adolescents. LGB youths who do not have access to local programs should be informed about Web sites created for LGB adolescents, such as the Trevor Project, where they can receive accurate information and communicate with other LGB youths in a safe, monitored setting (see Tools for Practice). PCPs can also point out positive LGB youth and adult role models in the community or nationally. In certain circumstances, for LGB PCPs to present themselves openly as role models to LGB youths and their families is also appropriate. Such disclosure should be done only after careful consideration of the physician's own confidentiality needs and how sharing such information might affect, either positively or negatively, the physician-patient/family relationship.

## SELF-DISCLOSURE, OR COMING OUT

LGB adolescents often reach a point in their development at which they feel a strong urge to disclose their sexual orientation to others, referred to as *coming out*. The process of disclosure to family and friends is often emotional and frequently traumatic. Adolescents who come out risk condemnation and rejection by family and peers. Disclosure can also result in physical violence both at home and at school. Therefore, coming out should be considered carefully, weighing the risks and benefits. If an adolescent expects a negative response from the youth's parents, then the adolescent should wait to disclose until legally and financially independent. However, many adolescents think that continuing to "live a lie" is intolerable and harmful to their self-esteem, and, therefore, they come out to their parents much earlier. Under no circumstances should a PCP reveal an adolescent's orientation to parents without permission. A PCP can play an important role in the process of disclosure by helping adolescents decide whether they are ready to come out to family or friends and helping them choose an appropriate time, place, and approach for disclosure.

## HEALTHY RELATIONSHIPS AND SEXUAL DECISION MAKING

Although some LGB youths manage to meet other LGB adolescents and establish friendships and dating relationships, most do not. PCPs should help connect LGB adolescents to local LGB teen support groups and LGB-supportive programs in the community if they exist. This task can be accomplished ethically without parental notification. PCPs can suggest national telephone hotlines or Web sites where LGB youths can receive accurate information and supportive counseling and communicate with other LGB youths. If these options are not available, then the PCP can serve as a supportive and reassuring lifeline until the adolescent is old enough to become independent and possibly move away to work or go to school in a community more accepting of LGB people.

LGB youths who are in relationships face many of the same questions as their heterosexual peers. "Am I in love?" "What do I want from a relationship?" "Do I really want to be in this relationship?" "How do I know if this is a good relationship?" "How do I get out of this relationship?" A LGB-supportive PCP or counselor can help adolescents reflect on and find answers to these questions.

As with other adolescents, many LGB youths know little about sexuality and how to make healthy sexual choices. Abstinence is always the appropriate option for adolescents who do not feel ready for a sexual relationship. LGB adolescents should understand that when they are ready for a sexual relationship, they can expect to lead healthy and fulfilling sexual lives. All adolescents who have decided that they are ready for a sexual relationship should be advised to limit their number of sexual partners and avoid mixing sex and alcohol or drugs so as to reduce their risk for infection, trauma, and sexual assault. Safer sex practices related to oral, vaginal, and anal sex should be reviewed in detail. LGB youths should also be aware that

*no always means no* in negotiating sex, and any forced or coerced sexual experience represents sexual assault. LGB youths should also understand that no set LGB repertoire of sexual behaviors exists and that they should engage only in those sexual practices with which they are comfortable.

## OPTIMISM FOR THE FUTURE

PCPs should challenge the belief of many LGB adolescents that their futures will be significantly limited by their sexual orientation. Referral of LGB adolescents to the *It Gets Better Project* Web site can be especially helpful (see Tools for Practice). Although some communities are clearly more accepting of LGB people than others, most LGB adults lead happy, healthy, and productive lives. LGB youths should be encouraged to pursue any career they wish. They should expect to have deep, long-lasting, and fulfilling relationships throughout their lives. They should expect to be respected and valued members of their communities. They also should understand that marriage and parenthood are enhancing the lives of thousands of LGB adults across the United States. Although growing up LGB is often challenging, the future should be seen as hopeful and exciting.

## PARENTS

Parents who learn of their child's LGB orientation often experience an intense mix of emotions. Some respond to this new understanding of their child with ready support and expressions of love. Many others feel varying degrees of guilt, shame, fear, anger, repulsion, and profound sadness. Many parents go through a deep mourning period, feeling as if they have lost the child they knew and loved. Some parents will reject or physically and emotionally abuse an LGB child. Parents are often as isolated from accurate information and supportive resources as are their children. PCPs should listen patiently and respectfully to parents' concerns and fears, acknowledging their pain and sense of loss. The PCP should emphasize the importance of their continued expressions of love for their child, especially at this time when many adolescents think that they will lose their parents' love and support. At the same time, the PCP can acknowledge that understanding and acceptance of their child's sexual orientation is an evolutionary process and will take time. Nevertheless, parents should be informed of the growing research-based understanding that parental rejection is a predictor of negative health outcomes for LGBTQ youth, including substance use, risky sexual behaviors, suicidal ideation and limited hopes for a happy future. Therefore, while acknowledging that negative responses to a child's disclosure of LGB identity may come from a place of genuine concern and love, it is essential that PCPs engage families in supporting their LGBTQ children through increased acceptance. Parents should be reassured that they did nothing wrong and that the pediatric profession has come to accept homosexuality and bisexuality as normal and healthy developmental outcomes. To decrease their isolation, parents should be referred to the online AAP patient education document titled *Gay, Lesbian, and Bisexual Teens: Facts for*

*Teens and Their Parents* (see Tools for Practice). They should be referred to relevant books, Web sites, and support programs for parents and families of LGB children. One of the most prominent national parent support organizations is Parents, Families and Friends of Lesbians and Gays (PFLAG), which has many local affiliate groups across the country. Parents should be reassured that American society as a whole is becoming increasingly accepting of LGB people. By providing love, support, and protection, parents should expect their child to achieve a happy, healthy, and rewarding adulthood.

The PCP should discourage any parental search for treatment that is directed at changing their child's sexual orientation. Such *reparative therapy* or similar religion-based *transformational ministries* are considered by the pediatric profession to be both unethical and dangerous. Finally, PCPs who think that they are unable to give LGB-supportive counseling to families should refer them to colleagues who have the time, comfort, and expertise to provide such support.

## ADVOCACY

One of the most important roles that PCPs can play in ensuring the health and safety of LGB adolescents is that of advocate. The advocacy role is essential, even lifesaving, because many LGB youths grow up in extremely hostile environments and have few, if any, advocates in their families or communities. PCPs' expertise is respected, and their offering of visible and confident support for LGB adolescents can promote increased community awareness, understanding, and acceptance, which are essential for the healthy development of these youths.

Advocacy can take place on many levels. On an individual patient level, PCPs can meet with families, school officials, social welfare agency staff, mental health care providers, and others to ensure that their patient is safe and accepted in the home, school, and community. They should also ensure that clinic and hospital policies and practices reflect respect for LGB patients. At a community level, PCPs can participate in educational forums that present the pediatric perspective that LGB orientations are normal and healthy. PCPs should be willing to go to schools and school boards, child welfare agencies, juvenile detention and correctional institutions, city councils, legislatures, and faith communities to advocate for policies and programs that specifically ensure the respectful treatment and address the special needs of LGB adolescents. National guidelines have been developed addressing these issues.

In addition, PCPs can advocate for school curricula and library holdings that reflect the diversity of students and their families, including diversity of sexual orientation and gender identity. Furthermore, they should advocate for the development and implementation of robust medical school, residency training, and continuing medical education curricula that include an in-depth consideration of the development, life experiences, and health needs of LGB adolescents and adults and provide the skills to work with these populations respectfully and effectively. This effort is especially important because, for many LGB youths, a supportive PCP may be the only lifeline they have

ensuring safe passage into a happy, healthy, and rewarding adulthood.

## WHEN TO REFER

- When an adolescent has acute or recurrent suicidal ideation
- When an adolescent is engaged in high-risk behaviors
- When the PCP decides that time, expertise, or comfort is insufficient to provide LGB-supportive care and counseling
- When an adolescent's physical, emotional, or developmental well-being and safety may be at risk because of family nonacceptance

Referral should be made only to pediatric, adolescent medicine, or mental health specialists who have experience in working with LGB adolescents and who accept same-sex attractions as normal and healthy. Referrals for reparative therapy or to transformational ministries are unethical and potentially dangerous.

## TOOLS FOR PRACTICE

## Chapter 77

# CHILDREN IN MILITARY FAMILIES

Timothy Wilks, MD (CDR, MC, USN)<sup>a</sup>;  
Beth Ellen Davis, MD, MPH (COL, MC, USA, Retired)<sup>b</sup>

### BACKGROUND

The military family is a modern experience. Before the Vietnam War, US service members were discouraged from having families. Entry into the armed services

was primarily through conscription at a young age. When military service became voluntary in 1973, the number of individuals looking for a career increased, and with them came their families. Currently supporting a population of families larger than its serving force, the Department of Defense (DoD) is now responding to the issue that has affected military service members and their families more than any other in the new millennium: the need to understand the effects of lengthy, recurrent, and dangerous deployments. With 2.2% of all US births, and more than 2 million children, military families and their unique concerns are not confined to the mission of the DoD, but extend to local communities, schools, child care, and health care systems. All pediatricians need to be aware of the physical and mental health needs of military children and the supports that are available to them.

In the past, the image of military families evoked a stereotypical profile, sometimes referred to as the “military family syndrome,” which described a rigid, authoritarian active-duty father, a stay-at-home submissive mother and wife, and “out-of-control” children with rootless identities exhibiting severe psychological problems. Subsequent research, including prospective studies of military versus nonmilitary children, failed to validate this profile and found no inherent psychosocial differences between military and nonmilitary children. In fact, 1 study of Navy families, for whom routine 6-month sea-duty deployments have been a way of life for years, indicated that children demonstrated increased responsibility, independence, and confidence compared with their peers without deployment experiences, suggesting that children develop a different and often beneficial parent-child relationship during parental deployment. Despite its varied components, the US military is a unified community with a strong sense of patriotism, pride, and self-sufficiency. Uniform attitudes and values, rank hierarchy, dress, and customs support a robust and resilient military culture.

### MILITARY LIFE

In addition to issues common in all US families, there are many aspects of military family life that are extraordinary: its diversity, frequent geographic relocations, opportunity to live in foreign countries, forced adaptations to new communities and schools, use of the largest single-payer health entitlement program (TRICARE) in the country, peacetime separations, remote unaccompanied assignments of service members, and dangerous, lengthy combat deployments. The DoD has 3.6 million members serving on Active Duty (AD) or Selected Reserve (SR), including the National Guard. Nearly half of these service members have children. Most children in AD households are younger than 6 years, whereas more than 60% of children in SR families are of school age. Geographically, AD families typically live within military communities where resources and support systems for young children are readily available. SR service members may be activated for service from civilian jobs in geographic areas quite remote from military resources and often have individual and family needs during military activation that may be unmet in their communities and specifically their schools. Of the service members with

Manuscript preparation was supported by the Health Resources and Services Administration (HRSA) of the U.S. Department of Health and Human Services (HHS) under grant T73MC00041, Excellence in Comprehensive Interdisciplinary Leadership Education: Enabling Children and Youth with Neurodevelopmental Disabilities to Achieve Their Dreams (UW LEND).

children, 5% (AD) to 9% (SR) are single parents. In 7% of families, both parents serve on AD. These families have additional needs when the military mission requires them to step away from parenting responsibilities. Thirty percent of the service members consider themselves nonwhite, non-Hispanic minorities. The diversity of US military families can be compared with that of other American families, and appreciation of various cultural contexts will help enhance understanding of family needs and provision of care.

### Relocation

Frequent relocations are commonplace for the military family and present significant challenges. At least 60% of military families have relocated at least once in the past 3 years. In a 2009 survey of AD families with deployed service members, 47% reported 3 or more moves in the past 5 years, significantly higher than SR families and the general US population. Frequent relocations affect spouse employment, school continuity, and child care, not to mention services needed for children with special health care needs. To help ease the economic burden of renting or owning a home, the AD service member is provided a housing allowance. Additionally, most military installations have housing available. Housing on military bases can provide a significant source of community support and reduce deployment challenges. Military housing neighborhoods are often filled with families and children in similar life stages, and neighbors take on the role of extended family members. Assignment to installation housing is determined by availability. Many times, families must live in the local community for several months before moving to installation housing, which can result in additional school relocations. Overseas assignments are also a common experience for service members and their families. At any given time, approximately 13% of AD members are stationed outside the US and its territories. The military family can move overseas with the service member in many locations, but some assignments require the AD member to be separated from his or her family for a 1- or 2-year unaccompanied assignment. For foreign locations that do allow families, the experience can be enriching. Families have the opportunity to travel and learn about new cultures. Often, overseas military installations provide many services (eg, housing, schools, supermarkets, department stores, restaurants) to families, and they can choose how involved in the local culture they want to be. Previously, communication with families back in the United States was difficult and expensive, but in the current digital age, the largest barrier is the time differences between countries.

### Schooling

Children in military families, on average, attend 6 to 9 different school systems between kindergarten and 12th grade. Many will change high schools more than twice. Traditionally this has led to less academic success and difficulties participating in competitive interscholastic activities. All 50 states and the District of Columbia, however, have now adopted the Interstate Compact on Educational Opportunities for Military

Children to ensure “uniform treatment of military children transferring between school districts and states.” This Interstate Compact addresses issues of enrollment, eligibility, and graduation parity between states. Many military families are unaware of the agreement, and many students resign themselves to less or fragmented school participation.

### Deployment

One aspect of military life that is well known and accepted among all service members is the need of the mission, which often requires time away from home and regular assigned workplace. Deployment is a temporary, 3- to 15-month movement of an individual or military unit away from his or her local work site, resources, and family to accomplish a task or mission. Deployments can occur as a peacetime activity or to support wartime operations. Peacetime deployments (separations other than war) include humanitarian missions such as when activated service members were sent to assist following Hurricane Katrina in 2005 or when more than 12,000 US service members were involved in the global response to the 2010 earthquake in Haiti. Operations other than war usually mean travel to safe locations, short duration, and interludes of rest and recovery between absences, and most military families cope well with these separations. Military families may also expect 3- to 6-month annual separations from their family service member for specialized schooling or training. Traditionally, unaccompanied tours of 1-year remote overseas assignments, when the family remains state-side, have not been defined as deployments. Wartime combat deployments, on the other hand, represent hostile, dangerous activity of usually long duration.

Before the wars in Iraq and Afghanistan, combat deployment was a rare occurrence for most military forces. Most families had never experienced the separation of a loved one to a hostile environment before 2001. Since then, families have experienced the most prolonged and repeated combat deployments in American history. Deployments have 3 main phases, each with predictable dynamics: predeployment, deployment, and postdeployment (or redeployment) (see Table 77-1).

### Effects of Deployment

The years since 2001 have provided most of the research on responses to war by US service members, their spouses, and their children. Complications related to war-combat stress disorder, traumatic brain injury, development of psychiatric illness, and increase in health risk behaviors can complicate family life for a child. Postdeployment emotional and behavioral responses by a soldier can range from typical short-term distress responses, such as change in sleep, decreased sense of safety, or social isolation, to the development of more serious psychiatric conditions such as post-traumatic stress disorder (PTSD) or depression. It is estimated that more than 30% of returning soldiers have experienced PTSD, depression, or traumatic brain injury. Comorbidities, such as aggression and alcohol misuse, are prevalent in up to half of those with impairment. Studies of spouses of service members indicate that deployment affects their well-being and marital

**Table 77-1**      **Phases of Deployment and the Role of the Pediatrician**

STAGES OF DEPLOYMENT	CHARACTERISTICS	PEDIATRICIAN ASSESSMENT	PEDIATRICIAN ANTICIPATORY GUIDANCE
<b>Predeployment:</b> from notification of deployment to actual departure	<ul style="list-style-type: none"> <li>• Often intense preparation of military units; requires extensive time away from family.</li> <li>• Decisions made about careers, financial adjustments, legal issues, and child care.</li> <li>• Experience with previous deployments may interfere with preparation for new deployment.</li> <li>• Can be confusing to children, who may not understand why separation is necessary and have no concept of what this change means.</li> <li>• Children at various developmental ages experience excitement, denial, worry, fear, and anger. Emotional withdrawal is not uncommon immediately before deployment.</li> <li>• Last-minute or recurrent goodbyes often increase tension.</li> <li>• Teens can be angry at the “selfish” nature of a service member’s job that takes the adult away from his or her role as parent, coach, and supporter.</li> </ul>	<ul style="list-style-type: none"> <li>• Assess for preexisting:               <ul style="list-style-type: none"> <li>• Family dysfunction</li> <li>• Mental health issues in parent</li> <li>• Special needs children</li> <li>• Recent family relocation</li> <li>• Recent divorce or remarriage</li> <li>• Previous problems during a deployment</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Discuss responsibilities and expectations of each family member during upcoming deployment.</li> <li>• Make plans and goals for family rather than “put lives on hold.”</li> <li>• Decrease likelihood of misperception and distortion.</li> <li>• Prepare for communication strategies and expectations, perhaps avoiding everyday contact.</li> <li>• Plan to maintain rules, rituals, and routines.</li> </ul>
<b>Deployment:</b> typically lasts between 3 and 15 months	<ul style="list-style-type: none"> <li>• Usually begins with a tearful going-away ceremony, followed by a period (usually 1–6 weeks) of emptiness and loss.</li> <li>• The intensity leading up to a goodbye can be overwhelming.</li> <li>• The sense of relief that the deployment has actually started can be confusing.</li> <li>• After about 6 weeks, most families try to establish and settle into a new routine.</li> <li>• The “midtour” rest and recuperation (R&amp;R) leave:               <ul style="list-style-type: none"> <li>• Is when the deployed service member can come home for 2 weeks.</li> <li>• Is often a difficult time for children.</li> <li>• May occur during the school year.</li> <li>• Is when children are often distracted by anticipation, excitement, and a short period of visitation, then have to say goodbye all over again.</li> </ul> </li> <li>• Many families describe deployment as “surviving, not thriving” despite trying to find resilience and strength.</li> <li>• For the month or 2 before homecoming:               <ul style="list-style-type: none"> <li>• There may be worry as well as excitement as new independence or self-reliance may have emerged into a “new normal.”</li> <li>• Family members are unsure how to reintegrate a deployed parent.</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Assess at-home parent and children for:               <ul style="list-style-type: none"> <li>• Adjustment (1–6 weeks after deployment)</li> <li>• Sleep regularity</li> <li>• School attendance</li> <li>• Mood problems</li> </ul> </li> <li>• Spend time in private conversation with adolescents to assess:               <ul style="list-style-type: none"> <li>• Adjustment</li> <li>• School performance</li> <li>• Mood</li> <li>• Risk taking</li> <li>• Role in family</li> </ul> </li> <li>• Offer free deployment video for youth</li> </ul>	<ul style="list-style-type: none"> <li>• Discuss responsibilities and expectations of each family member during upcoming deployment.</li> <li>• Make plans and goals for family rather than “put lives on hold.”</li> <li>• Decrease likelihood of misperception and distortion.</li> <li>• Prepare for communication strategies and expectations, perhaps avoiding everyday contact.</li> <li>• Plan to maintain rules, rituals, and routines.</li> </ul>

**Table 77-1**      **Phases of Deployment and the Role of the Pediatrician—cont'd**

STAGES OF DEPLOYMENT	CHARACTERISTICS	PEDIATRICIAN ASSESSMENT	PEDIATRICIAN ANTICIPATORY GUIDANCE
<b>Postdeployment (Redeployment)</b>	<ul style="list-style-type: none"> <li>• Often begins with “honeymoon” period of happiness and putting off the chores of the day.</li> <li>• Happiness of reuniting is mixed with needing to get reacquainted and deciding how to share the time lost.</li> <li>• “Block leave” is 30 days of vacation time given to the postdeployment unit, sometimes delayed after the actual return.</li> <li>• May not coincide with when family members have availability to leave school or work.</li> <li>• At-home spouse often wants some much-needed respite after a year of “full-time” parenting.</li> </ul>	<ul style="list-style-type: none"> <li>• Assess family for               <ul style="list-style-type: none"> <li>• Readjustment (1–6 weeks)</li> <li>• Parental mood</li> <li>• Post-traumatic stress disorder</li> <li>• Substance use</li> <li>• Marital discord</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Take time to communicate, get to know each other.</li> <li>• Spend time talking to each other.</li> <li>• Take time to make decisions, discuss changes in routine.</li> <li>• Lower holiday expectations.</li> <li>• Keep plans simple and flexible.</li> <li>• Don’t try to schedule too many things during the first few weeks.</li> <li>• Let absent parent “back into” the family circle.</li> </ul>

relationships. In a review of more than 250,000 Army wives, Mansfield and colleagues found that soldier length of deployment was associated with elevated depression, sleep problems, anxiety, acute stress reactions, and adjustment disorders in their wives. It is not surprising that the toll of lengthy and recurrent deployments has been reflected in marital discord. In 2008, a US Army Mental Health Advisory Team reported that the number of months deployed has a statistically significant linear relationship with married soldier reports on plans for divorce or separation, especially among the junior enlisted ranks. There is well-established literature across a range of populations to inform pediatricians about the effects of parental psychopathology and marital discord on child well-being, separate from the challenges faced by deployed service members and their spouses. Recognizing the increased vulnerability of children in these circumstances is a role general pediatricians have assumed for decades.

### **Coping With Deployment**

Despite limitations in data collection, researchers have compiled a few dozen studies to create the current profile of military children and their families coping with parental combat deployments. In 2008, Chartrand and colleagues studied preschool-aged children with and without a deployed parent and found increased behavioral symptoms in the preschoolers experiencing parental deployment. Flake and Davis found increased psychosocial morbidity in more than one-third of school-aged children with a deployed parent. At-home parental stress was reported to be very high in this group. Aranda and Davis queried military adolescents with and without a deployed parent, and both the teen self-reports and the parental

reports revealed increased stress in the deployed subgroup. Lester and colleagues and Barker and coauthors each provide evidence of the cumulative effects of deployment experiences as well as risk to children associated with psychological stress of either parent. Mansfield studied the electronic medical record data of more than 300,000 Army children and observed a dose-response pattern between deployment of a parent and increased child mental health diagnoses. At a population level, Gorman and colleagues found that rates of mental health, behavioral, and stress problems in children increased by 11% during parental deployment. A similar increase in psychiatric hospitalizations when a parent was deployed was found by Millegan. Two studies of youth, 1 in Washington State (Reed), and another in Iowa (Acion), showed those with a parent in the military had higher rates of risk-taking behaviors, including substance use and school-based violence. Although infants are yet to be studied, there is evidence of increased maternal stress related to pregnancy and childbirth when a service member partner was deployed. The first systematic review of military children, which included 9 studies, was published by White and colleagues in 2011 and, along with other studies, established consistent indicators of increased risk to military children, including emotional and behavioral problems, poorer academic achievement, and risk-taking behaviors. Risk seems to increase in a dose-dependent manner, based on the number and duration of parental deployments.

Although no specific or consistent pediatric diagnoses have emerged as indicators of the severity of chronic wartime stress, there are examples of significant distress: in testimony to Congress, there is evidence of increases in military preteen inpatient mental health stays,

and 2 studies suggested military families experiencing repeated or prolonged deployments, especially in young marriages with young children, were at risk for child maltreatment, specifically neglectful home environments. Over a decade, the extent to which combat deployments affect military children and their families is being compiled across the life span.

Three longitudinal studies are underway, one of which (Millennium Family Cohort Study, [www.millenniumcohort.org](http://www.millenniumcohort.org)) is a 20-year prospective study, and will substantially enhance our understanding of both the risks and resilience of military children during and after parental deployments.

### When a Parent Dies

The death of a parent or significant parenting figure during war is a catastrophically disorganizing event for a child, the surviving parent, and the family. It is one of the unspoken fears that family members endure during wartime deployments. Helping children understand parental injury or death requires a developmentally unique sensitivity. The pediatrician should assess the social-emotional reaction of the child in relationship to his or her developmental stage, follow the child over time, and support the remaining parent or life partner. The severity of parental injury is not directly related to the degree of child distress. It is important to consider not *how* the child is acting, reacting, or overreacting but for *how long*. It is common for children to demonstrate their grief for 4 to 6 weeks. Because of the devastating nature of parental disfigurement or death, most spouses or partners should be referred for social-emotional assessment and therapy to support their personal grief and to understand how to support their children. A specific resource for military families is the Tragedy Assistance Program for Survivors ([www.TAPS.org](http://www.TAPS.org); see Box 77-1). The pediatrician can encourage a surviving parent to seek military support through Decedent Affairs, the Chaplains' Office, or commanders of the military unit. This support is usually made available at the time the spouse or partner is notified of the death of her or his loved one.

## RESILIENCE

Resilience seems to play a major factor in all phases of deployment as well as military life. Protective factors include family readiness, "meaning making" of a situation, receipt of community and social support, acceptance of the military lifestyle, ability of the at-home parent to develop self-reliant coping skills (see Box 77-1), and adoption of flexible gender roles. Children who have supportive caregivers, school environments, and adults who understand their military situation are more able to effectively recruit coping skills that augment family supports. Evolving understanding of these factors supports the role of systematic approaches to prevention and care of the military-connected child. As programs to support children and families are developed, it is important that they are evaluated for their effectiveness similar to the family-centered, preventive care program developed by Lester and colleagues that showed a statistically significant decrease in anxiety and depression measures and led directly to increases in healthy family functioning.

## BENEFITS OF MILITARY SERVICE

Even in the midst of ongoing deployments, military families, regardless of service or component, appreciate the advantages of military life, including adequate free housing, an “on post” community with shopping, accessible child care and schools, low cost or free medical care, community services including free financial and behavioral counseling, emphasis on recreational facilities, subsidized educational opportunities, relatively stable family income, shared identity and mission with peers as well as senior leaders, and a feeling of patriotism and national contribution.

## HEALTH CARE IN THE MILITARY

The AD service members and their families receive significant health care entitlements under TRICARE, including inpatient, outpatient, primary, and subspecialty care; therapies; medications; and equipment. The administrative agent for TRICARE varies with 3 regions (North, South, and West) based on a contracting process and includes both military treatment facility (MTF) or “direct care” and a network “purchased care” component. There are 149 MTFs in the United States and around the world accounting for 63% of DoD pediatric beneficiary care and supporting Army, Navy, and Air Force military pediatric residencies, subspecialty pediatrics, pharmacy, behavioral health, and ancillary care services. The medical coverage exclusions are regulated by Congress and implemented by the regional administrative agents. The Defense Health Agency recently concluded that the Military Health System is generally meeting the needs of pediatric beneficiaries, but outlined several opportunities for improvement. There were recognized gaps noted in several areas, including transferring care when children move between regions, using preventive care programs, and providing habilitative care.

Several options are given to military families regarding their medical entitlements. TRICARE Prime requires the assignment of a primary care manager (PCM). The PCM provides a medical home as the primary care medical provider and must submit authorization requests for consultation and procedure approval. The MTFs and hospitals are the preferred locations for family members under TRICARE Prime. There are no out-of-pocket expenses for TRICARE Prime. Additional options, TRICARE Extra and Standard, allow for more choices to the beneficiary but also require varying levels of out-of-pocket expenses, with copays and deductibles. Perhaps one of the most significant benefits under TRICARE is the mental health option or Behavioral Health Portal. Family members can be seen up to 8 times by any mental health provider in the TRICARE network without a consult from a PCM. This benefit allows for improved access to mental health services for all military family members. Family member dental care is not covered under TRICARE, but additional coverage can be purchased for a nominal fee. Interested providers should consult Web site references listed in Box 77-1 for the most current information regarding TRICARE benefits.

To prevent moving a family with a dependent who requires significant medical or educational services to a medically underserved area, the military requires

AD service members and their families to enroll in the Exceptional Family Member Program (EFMP). The EFMP is designed to help select appropriate service member duty assignments and continue to meet family members’ health care needs without detriment to the service member’s career. Dependents enrolled in EFMP are potentially eligible for services under the Extended Care Health Option (ECHO). Habilitative equipment and skilled nursing care are provided as part of the ECHO program. The Autism Care Demonstration Project provides intensive autism supports such as applied behavioral analysis and respite care for children with autism who are TRICARE eligible.

Children of military members require an identification card at age 10 years and are eligible for care up to age 23 if they remain full-time students. TRICARE Young Adult (TYA) is a premium-based program available for children 23 to 26 years of age. For children with chronic lifelong medical issues resulting in diminished capacity to live independently, the AD or retired service member has the opportunity to request indefinite medical support for that family member. After a service member retires, the family continues to be eligible for TRICARE retired medical benefits.

## RECOMMENDATIONS FOR PEDIATRICIANS

To support children of military families, a nondeployed parent needs to feel in control and to have support. The pediatrician can encourage the at-home parent to stay healthy and connected, including sharing experiences and finding opportunities for personal growth, respite, and spiritual wellness. If needed, the pediatrician can support and help the parent find a mental health professional. One resource, [www.MilitaryOneSource.com](http://www.MilitaryOneSource.com), is available for pediatricians and military spouses to access adult mental health services regardless of location or service. Pediatricians should be familiar with this Web site to help family caregivers with their own emotional needs. Many of the deployment-specific resources available to AD families can be accessed on this Web site for activated National Guard and Reserve families, including Military Family Life Consultants, chaplains, legal assistance, social work services, and New Parent Support services. In addition to direct contact with a case manager or mental health locator, at-home parents can request free parenting and support books from the OneSource library, and can find parent support groups in their local areas.

The needs and concerns of the military family vary depending on the specific phase of deployment. Table 77-1 shows the phases of deployment and the role of the primary care pediatrician in providing appropriate anticipatory guidance. Pediatricians can connect a family struggling with deployment to resources available in the military community. Some military bases have deployment-related respite or child care services available. School-aged children can participate in Operation Camp Purple, which employs peer relationships to build resiliency.

Understanding military culture and asking initial questions of a child or teen who has a military parent can help unveil etiologies of academic problems, poor

**BOX 77-2 Indications for Referral**

Pediatricians should consider referral of a child/family to a mental health professional when

- They have tried reassurance and helping the parent cope using a psychoeducational intervention or generally supportive counseling, which is not working after 2 visits
- They feel uncomfortable about their own counseling and psychoeducational skills
- Child behavior has become more extreme or continues for up to 3 months after the deployed parent has returned home
- There is a significant change in behavior or a drop in school performance
- There has been an injury or death of a deployed parent

peer interactions, or risk-taking behaviors. Pediatricians need to be able to access a “virtual toolbox” containing health and mental health screening tools to help identify children in need of additional services. Box 77-2 contains additional guidelines for pediatricians to consider referral to a mental health professional.

Pediatricians are on the front line in meeting the needs of military families. By understanding the strengths and challenges of living in a military family, physicians can recognize opportunities to respond within the context of the pediatric medical home.

**Chapter 78****HOMELESS CHILDREN**

Patricia McQuilkin, MD; Jason R. Rafferty, MD, MPH, EdM

Although homelessness brings to mind the stereotype of a man panhandling on a street corner, in fact, single women and their children comprise a significant proportion of people who are homeless. Pediatricians will likely encounter children in their practices who are experiencing or have experienced homelessness. With the passage of the McKinney Act in 1987, the US Department of Housing and Urban Development (HUD) defined a homeless individual as one “who lacks a fixed, regular, and adequate nighttime residence.”

This definition has been criticized for not acknowledging the dynamic nature of homelessness, particularly because it tends to exclude families and youth. To avoid the risks of living on the streets, homeless families and youth are more likely to be in and out of shelters, residing in vehicles or motels, or “couch surfing” with friends and relatives. Consequently, by adding the education subtitle to the renamed McKinney-Vento Act, the Department of Education included children living in motels and those who share temporary housing to this definition. In 2011, HUD released the Final Rule Defining Homelessness, which incorporates families who are in unstable housing situations, are fleeing domestic violence, or may face homelessness in the next 14 days.

In some cases, the family unit as a whole experiences homelessness. In others, an “unaccompanied youth” may not be in the custody of his or her family and may be physically disconnected from them. These youth may leave their family, either voluntarily (“run-away”) or because family member(s) force them out (“thrown-away”), have no legal right to where they are staying (“doubling up”), or no access to shelter at all (“street youth”).

Knowledge of a child’s past and present housing status is important to clinical care. Homelessness can contribute to toxic stress; affect the health, psychological, and developmental well-being of a child; and

present barriers to health care access and treatment adherence.

## NUMBERS OF HOMELESS

Between 2.3 and 3.5 million Americans experience homelessness at least once per year. Single adults, some of whom are chronically homeless constitute 49% of this population. Families with children comprise 34% of the homeless population, and as the gap between income and affordable housing widens, the number of families without homes is increasing. As a result, 1.6 million children will experience homelessness during the course of a year. According to HUD “point-in-time” data, on any given night, approximately 200,000 children and youth (defined as those up to 24 years of age) will have no place to stay. About 76% of these children and youth are living with their homeless families. The remaining 23% are “unaccompanied youth.” It should be noted that this point-in-time count used the original, narrow HUD definition of homelessness so these are likely underestimates that do not take into account “doubling up” and other unstable housing situations. This leaves hundreds of thousands of homeless children invisible to policymakers and the public.

The Department of Education is also mandated to keep a count of homeless children enrolled in US public schools. In 2013, approximately 2.5 million children experienced homelessness. This represents approximately 1 in every 30 US children based on census data. Despite the use of a broader definition, this figure also is likely an underestimate, given that such children may not be consistently enrolled in school and there is an incentive against disclosure because it might affect a child’s school district assignment.

### Homeless Families

Who are these homeless families? Among adults in homeless families, 29% are working. A typical sheltered homeless family consists of a mother in her late 20s with 2 children and limited education. Among children in homeless families, 42% are younger than 6 years. An estimated 84% of these families are headed by women. Most are minorities, with 43% being African American, 38% white non-Hispanic, 15% Hispanic, and 3% Native American. Nearly all mothers experiencing homelessness have a history of interpersonal violence, and as a result, suffer from severe depression (50%), posttraumatic stress disorder (PTSD; 33%), and substance abuse.

It is estimated that 75% of homeless children and families may be “doubling up” with friends or relatives, or living in cars or motels. These families often have a strong incentive not to disclose their living situation because it may lead to eviction or complications with the children’s school district.

### Unaccompanied Youth

Homeless or unaccompanied youth comprise approximately 8% of the total homeless population and 23% of all homeless children and youth, according to HUD point-in-time counts. Among programs that count homeless youth, the US Department of Justice (DOJ) Office of Juvenile Justice and Delinquency Prevention data are most often cited. This is because they include

aggregates of diverse and relevant sources, including surveys of households, juvenile residential facilities (detention centers, group homes, etc), and law enforcement agencies. They define “homeless” as being away from home without permission for more than 1 night if the child is younger than 15 years or 2 nights if the child is older. Their most recent study reported an estimated 1,682,900 unaccompanied homeless and runaway youth in 1999. This number is equivalent to estimates by the Research Triangle Institute based on responses to the Centers for Disease Control and Prevention’s Youth Risk Behavioral Survey published in 1998.

According to DOJ data, unaccompanied homeless youth include equal numbers of boys and girls, with the majority of them being 15 to 17 years old. Seventy-one percent of these youths were categorized as being in immediate danger because of factors such as substance dependency, sexual or physical abuse, living in an area of criminal activity, or young age ( $\leq 13$  years). They are 7 times more likely to be victims of violent crimes; 30% stayed within 10 miles of home and 83% remained within their state of residency. Across studies, between 20% and 40% of homeless youth identified themselves as lesbian, gay, bisexual, or transgender (LGBT).

Recently, 9 sites across the country were selected as part of a federal interagency initiative, Youth Count!, to pilot new methods to improve counting of unaccompanied homeless youth, particularly through increased engagement with LGBT services.

## CAUSES OF HOMELESSNESS

Family homelessness is caused by a combination of factors including poverty, low-paying jobs, unemployment, lack of affordable housing, and interpersonal violence. Vulnerable families with little social support can become homeless when seemingly minor triggers result in major catastrophe. A 2005 study by the Vera Institute of Justice found that families who entered the New York City shelter system experienced remarkably high rates of disruption in their lives in the 5 years before becoming homeless. Sixty-nine percent had a job loss, 43% had physical health problems, 39% had emotional health problems, and 21% were victims of interpersonal violence. The economic recession during the period 2007 to 2010 caused one of the deepest downturns in the labor market in postwar history. This resulted in a record high number of housing foreclosures, which compounded the problem of homelessness even further. As a result, the number of homeless children increased by 38% during this period, to include many who were previously in the middle class.

Only 1 in 5 unaccompanied youth are reported missing; of these, 47% to 62% indicated that a family member told them they were no longer wanted. Most unaccompanied youth leave home to escape dysfunctional or abusive family situations, or are coerced into leaving by adults at home. There is a strong relationship between abuse and subsequent homelessness, with estimates of 17% to 35% of such youth reporting sexual abuse and 40% to 60% reporting physical abuse. Other family-related factors include neglect, parental

substance abuse, and conflict over sexual orientation, sexual activity, or pregnancy. Residential instability is another contributing factor, with the majority of unaccompanied youth having a history of out-of-home placement; specifically, 70% of homeless unaccompanied youth have spent time in a foster family, group home, or other residential facility. Nearly half of children in foster care report a history of running away, and 14% to 50% experience homelessness.

### Poverty

A clear and direct correlation exists between poverty and homelessness. The majority of homelessness in the United States is caused by the gap between income and the cost of housing. In 2009, 17% of all American families and 34% of all single-parent families lived below the federal poverty line. According to HUD, families with the following characteristics are in the category of worst-case housing needs: those who rent, have incomes less than 50% of the median family income in their community, pay more than one-half of their income for housing, and do not receive federal housing assistance. These families are at the highest risk for becoming homeless. Since this statistic was tracked in 1991, approximately 5% of households have fallen within this category. Children reside in 36% of households with worst-case housing needs.

Full-time employment is not a guarantee against homelessness. Of families with worst-case housing needs, 41% have at least 1 full-time worker. Despite being employed, many families do not earn adequate wages. Approximately one-fifth of all jobs in the United States do not keep a family of 4 out of poverty. More and more individuals are employed by service industries, such as hotels and restaurants, which pay minimum wage and often provide only part-time work, with few or no benefits. This circumstance puts housing out of reach for many families. Fair market rent is calculated by HUD as “the amount that would be needed to pay the gross rent (rent plus utilities) of privately owned, decent, and safe housing of a modest (nonluxury) nature with suitable amenities.” The National Low-Income Housing Coalition defines housing wage as the “hourly wage necessary to pay the fair market rent for a 2-bedroom home while spending no more than 30% of income on housing costs.” Nationally, the housing wage in 2005 was \$15.78, with a range of \$8.10 to \$29.54. The national housing wage is more than triple the minimum federal wage.

### Housing Shortage

A serious gap continues in the number of units needed to house low-income families and the amount of affordable housing. The National Income and Housing Coalition concluded that the United States is experiencing a significant and prolonged shortage of affordable housing. At least 1.7 million housing units are needed to fill this gap. Housing costs have also been outpacing wages. A full-time worker earning minimum wage currently cannot afford a 1-bedroom apartment at fair market wage anywhere in the United States. This situation has been exacerbated by the federal government’s decreased role in providing low-income housing over the last 20 years. Federal

support for low-income housing fell 49% between 1980 and 2003, and only 30% of persons who are eligible for low-income housing assistance receive this subsidy. Since 1995, more than 200,000 subsidized housing units have been lost.

### Interpersonal Violence

Fifty-four percent of cities surveyed in 2005 identified interpersonal violence as the leading cause of family homelessness. A study in Minneapolis found that 40% or more mothers revealed domestic violence to be a major cause of their family’s homeless situation. These families are often headed by women who are fleeing a violent situation at home, and have little in the way of social or financial support. They often are unable to obtain credit or child support. They may have difficulty accessing resources because they are afraid of being discovered by their abusers. The physician needs to be aware that interpersonal violence is an important cause of homelessness for families.

Interpersonal violence is also a major cause of homelessness for unaccompanied youth. An important subgroup, unaccompanied youth, consists of persons who are asked to leave home or are not allowed back home by a parent or guardian. Family conflict and violence are the primary causes of their homelessness, and nearly half have been physically or sexually abused.

## EFFECT OF HOMELESSNESS ON CHILDREN’S HEALTH

Homeless children have significantly higher rates of acute and chronic illness compared with housed children. Several factors are responsible for this disparity.

Homelessness can cause illness and aggravate existing health conditions. Living conditions in shelters are often crowded; children are more likely to be exposed to contagious diseases, and they often have poor access to health care. Families living in shelters are living under stressful conditions, which can exacerbate illness. Homelessness contributes to toxic stress, which has adverse effects on child health and development. (See Chapter 68, *Children Exposed to Adverse Childhood Experiences*.)

Lack of access to primary and preventive care is a major issue for homeless families. Nearly 1 in 10 homeless children reports that he or she has not seen a physician in the past year. Lapses in care can lead to lapses in treatment of chronic illness and decreased vaccination rates. Many homeless families use the emergency department as their primary source of health care. The lack of preventive care leaves various medical problems untreated, which in turn leads to more use of the emergency department.

Lack of medical insurance coverage is another barrier to homeless children obtaining primary and preventive care. One study showed that 58% of homeless children lacked health insurance compared with 15% of housed children.

### Homeless Children and Rates of Illness

Health risks related to homelessness begin during the prenatal period. Statistics show increased morbidity and mortality rates related to lack of prenatal care,

poor nutrition, stress, and exposure to violence, as well as increased substance abuse. One study revealed that 20% of infants born to homeless mothers were preterm. The risk of a homeless woman giving birth to an infant weighing less than 2 kg was 6 to 7 times that of the control group. Severity of homelessness predicts low birth weight and preterm births beyond its correlation with delayed prenatal care and other risk factors. Among pregnant homeless adolescents, a frequent history of severe sexual abuse and early intravenous drug abuse correlates with poor health outcomes in the newborn.

Homeless children have 4 times as many acute illnesses as housed children. They suffer from twice as many ear infections, 4 times as many respiratory infections, and 5 times more stomach problems. Because homeless families live in crowded conditions, the risk of acquiring upper respiratory tract infections, diarrhea, and otitis media is increased. One study revealed that homeless children had a 50% increased rate of otitis media compared with the national average (27% vs 18%). This increase was probably the result of greater exposure to upper respiratory tract infections and secondhand smoke. Because of a lack of consistent medical care among the homeless, otitis media is often undiagnosed and untreated, leading to possible hearing loss.

Homeless children also suffer from increased rates of chronic illness, exacerbated by their living conditions. Asthma, the most common chronic illness during childhood, is aggravated by the difficult living conditions in shelters, such as crowded conditions, increased exposure to respiratory infections, stress, and poor access to health care. The prevalence of asthma among a random sample of homeless children in New York City was found to be 39.8%, more than 6 times the rate for other children. Asthma in homeless children was more likely to be severe and undertreated.

Other conditions that are more prevalent in homeless children include poor dentition. Homeless children are more likely to have dental caries and severe tooth decay compared with housed children. According to the National Health Care for Homeless Providers, the rates of poor dentition and dental caries are approximately 10 times greater among homeless children than among the general population.

The risk of homeless children acquiring ectoparasitic infections such as lice and scabies is higher. They are also at increased risk for elevated lead levels.

### Oral Health

The most common unmet health need among all children is adequate dental care. This is particularly true among homeless children who are at high risk for tooth decay (5 times more common than asthma in the homeless population). One in 3 homeless children have not had dental care in the past year compared with 1 in 5 among housed children. Major contributing factors include the limited number of dentists who participate in public insurance, a general shortage of the dental workforce, long wait times after scheduling an appointment, and an uneven geographic distribution that neglects low-income areas.

### Homeless Adolescents

Regardless of whether homeless adolescents are with their families or unaccompanied, they represent a particularly high-risk population. Adolescence is a challenging time in any circumstance as teenagers learn to navigate new independence and identity alongside rapid physical change. In addition, decision-making and problem-solving skills are still developing. The lack of economic, social, and emotional resources (including supportive adult relationships) faced by homeless adolescents can interfere with one's developmental trajectory, leading to dangerous consequences and high risk-taking behavior. Adolescents and young adults are overrepresented among unaccompanied youth, and are at an extremely high risk for victimization and are least likely to be connected to service agencies. This can lead to very concerning physical and mental health outcomes. (See section on The Health of Unaccompanied Youth later in this chapter.)

In general, among homeless adolescents, the incidence and prevalence of human immunodeficiency virus (HIV) infection, *Chlamydia*, herpes, and hepatitis B and C are increased. Increases may be caused by lack of access to educational and prevention programs, lack of condom use, multiple partners, increased drug use, and sexual victimization. Homeless youth are at high risk of substance abuse, mental illness, and bloodborne infections. Mortality among homeless youth is approximately 11 times the expected rate based on age and sex and is mainly caused by suicide and drug overdose.

Sexual minorities are overrepresented among homeless adolescents, especially unaccompanied homeless youth. It is estimated that 2% to 40% of homeless youth identify as LGBT and their voluntary or involuntary "coming out" was the most common reason for becoming homeless, specifically a "throwaway." The LGBT homeless youth population is at much greater risk for violence and negative health outcomes than their heterosexual peers. In particular, they are at risk for early onset of sexual activity, involvement in prostitution or survival sex, multiple partners, and other risky behaviors leading to elevated HIV rates, substance abuse, mental health problems, and physical and sexual victimization.

### Homeless Children and Nutrition

Homelessness and hunger commonly coexist. Homeless children suffer from lack of access to food and good nutrition. Children without homes are more than twice as likely as other children to experience hunger. More than one-third have been forced to skip meals and two-thirds of these children worry about having enough to eat. It is well-established that lack of good nutrition can affect a child's behavior, school performance, and cognitive development.

Homeless children are 3 times more likely to experience iron-deficiency anemia caused by poor nutrition. One study reported a 52% rate of obesity, 45% rate of anemia, and 36% rate of failure to thrive among homeless children. Given the importance of adequate nutrition for development in the infant and young child and the risk factors associated with obesity in later life, these findings are disturbing.

### Minority Homeless Youth

Black children in the United States have disproportionately higher rates of homelessness than white and Hispanic children. Minority homeless children also have poorer health outcomes compared with their white counterparts, even when family income and health insurance coverage are controlled. For example, black homeless children are 49% more likely to have asthma and 21% more likely to have activity limitations compared with white children. Racial disparities in health outcomes persist until family income falls below 200% of the poverty line.

Many mechanisms underlie the relationship between race and poor health among homeless children. Interpersonal and institutionalized discrimination contribute to differential access to medical services, dental care, and shelters. In fact, Hispanic homeless children have been found to have the poorest overall access to primary and preventive care. Furthermore, although national studies find no racial or ethnic differences in new homelessness, local studies tend to suggest that such minorities are overrepresented. This discrepancy may be the result of a sampling bias, reflecting the fact that black and Native American youth are more likely to be on the streets because of low shelter access.

Ultimately, internalized discrimination, secondary to a child witnessing first hand the devastating effects of personal and institutional inequalities, is believed to cause physiologic stress, which has a negative influence on chronic disease. In older children, such stress reinforces feelings of injustice, powerlessness, and victimization that lead to violent behaviors and mental illness.

### EFFECT OF HOMELESSNESS ON CHILDREN'S BEHAVIORAL HEALTH

Developmental, educational, and psychological outcomes in homeless children are equally worrisome. Compared with other children, homeless children are 4 times as likely to have developmental delays, twice as likely to have learning disabilities, and twice as likely to repeat a grade because of frequent absences and school changes. The majority of both homeless mothers and their preschool children exhibit delays in at least 1 of the following areas: auditory comprehension, verbal expression, reading, and writing.

Unaccompanied youth are at particularly high risk for victimization, traumatic stress, and poor mental health outcomes, which is discussed specifically in the section entitled "The Health of Unaccompanied Youth."

### School and Homeless Children

Children experiencing homelessness face huge barriers to obtaining education. These children experience significant educational disruption because of multiple relocations and school changes. Such disruption causes lower levels of academic achievement. One study showed that among homeless children in grades 3 to 12, only 48% were proficient in math and 43% were proficient in reading. Thirty-six percent of homeless children will repeat a grade, and less than 25% of homeless children will graduate from high school.

Buckner and coworkers compared the school experiences and academic achievement of adolescents in families who experienced homelessness with permanently housed adolescents whose families received public assistance. Formerly homeless students had more school mobility, were more likely to repeat a grade, and had worse school experiences by maternal report and lower plans for postsecondary education by self-report. Homelessness was associated with declines in achievement during the period of maximal residential disruption. Days absent from school were hypothesized as the mediating link between homelessness and academic achievement.

In an effort to improve the educational opportunities of homeless children, the McKinney-Vento Homeless Assistance Act of 2001 was created. It requires that children and youths experiencing homelessness are immediately enrolled in school and have educational opportunities equal to those of their nonhomeless peers. The statute requires every public school district and charter holder to designate a *homeless liaison* to ensure that homeless students are identified and that their needs are met.

### Homeless Children and Behavioral Health

Children who experience homelessness have 3 times the rate of emotional and behavioral problems as their housed peers. This is largely because of the amount of stress and trauma that these children experience and witness.

Twenty percent of homeless preschoolers have emotional problems requiring intervention. One-third of homeless school-age children have a major mental disorder that interferes with daily activity compared with 19% in the general population. Forty-seven percent have anxiety and depression compared with 18% in the general population, and 36% are aggressive compared with 17% in the general population. Less than one-third who might benefit from treatment are receiving assistance.

Evidence that homeless youth may suffer disproportionately from behavioral and psychological problems is persuasive. Once a child is homeless, an increase can be found in the number of psychological diagnoses, including drug- and alcohol-related conditions. Trauma is a common experience among homeless youth. Trauma resulting from exposure to violence may be a mediating factor, with 83% of homeless youth older than 12 years being exposed to violence and 25% having witnessed violence in their family. The risk of sexual and physical victimization is increased among homeless adolescents, leading to increased risk of posttraumatic stress syndrome. One half of homeless youth report being physically abused, and one third experience sexual abuse. Homeless adolescents are 6 times more likely to meet criteria for conduct disorder, major depressive disorder, posttraumatic stress syndrome, alcohol abuse, or drug abuse. After homelessness, involvement in criminal activity is common.

"Attachment" describes the emotional connection between a child and caregiver, particularly the desire for closeness and security in the face of stress and separation. Therefore, the health and emotional well-being of a child is closely linked to the emotional

well-being of his or her parent. Increased levels of depression in homeless parents adversely affects their ability to provide supportive caregiving (including breastfeeding of infants), consistent social interaction, and engagement in enriching activities. This leads to an increased stress response in the child which contributes to poorer cognitive, emotional, and developmental outcomes. Unaccompanied homeless girls have much higher rates of teenage pregnancy than their peers, which is especially concerning given that homeless adolescents are at elevated risk for mood disorders with little access to resources and supports.

## THE HEALTH OF UNACCOMPANIED YOUTH

Violence is the top reason why youth leave home and disconnect from their families. The DOJ study focusing on unaccompanied homeless youth found that 21% were physically or sexually abused in the year before leaving home. A study in Seattle found that among homeless and runaway adolescents, 82% reported experiencing physical abuse, 43% family neglect, and 26% sexual abuse.

In addition to being exposed to or experiencing violence before leaving home, adolescents are at high risk for being retraumatized in shelters, and especially on the streets. A study in Los Angeles found that 1 in 4 homeless adolescents had been shot at (7% wounded), 1 in 5 had been stabbed, and 1 in 6 sexually abused. In general, as many as 43% of adolescent men and 39% of adolescent women report having been assaulted with a weapon while living on the streets. For men, the greatest risk factor for engaging in aggressive behaviors is having been physically victimized.

Unaccompanied young women and sexual minorities are particularly susceptible to sexual victimization. As many as 43% of homeless adolescents in Los Angeles reported having engaged in “survival sex,” which is the exchange of sexual acts for necessary resources. Risk factors for survival sex include a history of physical or sexual abuse, depression, the need to obtain income (often for medical care), and drug/resource sharing. LGBT homeless youth are 3 times more likely to engage in survival sex than their heterosexual peers. Sexual assault is a particular concern, with rates reported to be as high as 42% among female runaways and 59% among LGBT homeless youth (compared with 33% among their heterosexual peers in that particular study). Such behaviors have contributed to alarmingly high rates of sexually transmitted infection (estimated prevalence 50%–70%). Homeless and runaway adolescents are at 2 to 10 times greater risk for HIV infection. The longer they are homeless, the less motivated they are for HIV prevention, and may report the belief that they would be better off contracting HIV because it would make them eligible for housing funds specifically for HIV-positive people in need.

Unaccompanied youth experience almost constant fear of victimization, which is accompanied by the stressors of living in a shelter or on the streets, obtaining necessary resources to survive, and the loss of routine and predictability in their life. Such experiences

have consequences for mental health (depression, anxiety, and stress disorders), substance abuse, and reduced resiliency, and they may interfere with the individual's ability to identify and develop positive relationships. Most unaccompanied adolescents meet criteria for mood disorders, especially major depression, and more than one-third meet PTSD criteria during their lifetime. Attempted suicide rates (18%–48% across studies) are consistently higher for unaccompanied homeless youth than their normative peers with nearly half of heterosexual homeless youth describing suicidal ideation. Among LGBT homeless youth, that rate is as high as 75%.

Homeless youth may abuse substances to help withstand the severe hardships they face both at home and on the streets. The prevalence of substance use across studies ranges from 70% to 90%. Rates of marijuana abuse were 6 times higher than those for housed peers, and cocaine abuse was 35 times higher. Substance abuse is especially high among “street youth,” with 1 study stating that 94% used tobacco and alcohol, 97% used marijuana, 73.4% used amphetamines, 55.5% used cocaine, and 39.5% used heroin in the last year.

## CARE OF HOMELESS CHILDREN AND FAMILIES

### Homeless Families

Families may not identify themselves as homeless. The children may actually be attending school, yet go “undetected.” It is important to ask questions about housing to identify homeless families. This can be a part of universal previsit screening, using a tool such as Kemper's Family Psychosocial Screen.

Once a family is identified as homeless, the most important issue is ascertaining that all children are living in a safe environment. If not, then the family should be assisted with making contacts with a local family homeless shelter system, welfare agency, or charitable institution that can provide temporary housing. It should be noted that family shelters may not allow adolescent boys or adult fathers to stay, which forces male members to break off and find shelter elsewhere. Two-thirds of cities polled in a 1995 survey reported that they do break up families because of such regulations. These families will also need assistance in applying for health, nutrition, and social services and, if the child is uninsured, for Medicaid.

All children need to undergo a thorough medical, developmental, and psychological history and a physical examination to identify medical conditions associated with homelessness, the factors that led to homelessness, and needs for medical care. Particular attention should be paid to health care maintenance, including immunizations and lead testing, and to the diagnosis and treatment of chronic medical conditions. Clinic care that is offered to children while they are homeless should be comprehensive, meeting the criteria of a medical home. In addition to primary pediatric care, clinic care should include 24-hour telephone access, referral to subspecialty care, developmental and psychological evaluation and treatment, medication and medical devices, and case management.

Asthma is overrepresented among homeless children. Children often require aggressive treatment, and parents may need comprehensive education to avoid hospitalization, excessive emergency department use, and school absenteeism for their children. A child who is not sleeping at night or keeping other family members awake because of coughing can exacerbate the stress of being homeless.

Children of families living in shelters may have frequent acute illnesses as a result of living in close quarters with other families. In treating upper respiratory infection, gastroenteritis, otitis media, and tinea, a helpful approach would be to instruct parents about infection control measures in addition to applying standard treatment regimens. Outbreaks of certain illnesses, such as varicella or hepatitis, may require contacting shelter personnel or the local department of health to initiate infection-control measures.

When a parent brings in a child who has a minor acute illness, it is important to use the visit as an opportunity to perform a thorough medical assessment and initiate any needed treatment and referral. Follow-up can be problematic for homeless families, and any delay in initiating a comprehensive treatment plan may impede needed health care.

Homeless children face constant traumatic stress and uncertainty (lack of routine) as well as high rates of mental health concerns and parental depression. These have all been shown to adversely affect cognitive, emotional, and social developmental trajectories. Therefore, routine behavioral and developmental screening is essential with a validated age-appropriate tool, such as the Pediatric Symptom Checklist for school-age children and adolescents. A licensed mental health clinician who has experience working with homeless families should be identified for follow-up referrals, if necessary.

In addition to referrals for developmental assessment or psychological problems found in children, referring parents for counseling may also be necessary. Some families are homeless because of severe parental mental health problems or substance abuse. A parent may become depressed as a result of being homeless. Mental health concerns and stressors of caregivers should always be addressed so as to optimize the environment needed for a child's well-being.

One of the most common reasons for a woman and her children becoming homeless is interpersonal violence. Women must be queried about this issue. (See Chapter 68, *Children Exposed to Adverse Childhood Experiences*.) Clinicians should be aware of local resources for victims of interpersonal violence so that any necessary referrals can be made. Moving a family into an interpersonal violence shelter may be necessary if the batterer is a threat.

Chronic medical conditions are often not treated properly. This is because homeless families frequently move, resulting in multiple clinicians and discontinuity of care. This circumstance may lead to underreferral, overreferral, and undertreatment. For example, a child may be referred multiple times to specialists for the same problem; the diagnostic workup may be restarted with each referral; the specialist may never reach the point of implementing an adequate treatment plan. While the child is homeless, a more practical

approach may be to initiate the medical workup in the primary care setting, and arrange for specialty referral once the family enters permanent housing.

When a family is moving out of a shelter into permanent housing, they will often need assistance in locating medical care in their new community. This involves helping to identify a new medical home and transferring medical records to the new physician.

### Unaccompanied Youth

Distrust of adults is very common among homeless (especially victimized) youth, which limits initial contact with clinicians, even when they are readily accessible. In addition to victimization by adult figures, distrust may also be based on prior experience or fear of being forced into placement (foster care, hospitals, or detention centers) instead of having their needs met. Therefore, outreach is critical because these youth are unlikely to present to a traditional outpatient clinic.

The US General Accounting Office found that health services were not a reported priority among programs providing outreach and shelter to homeless youth. However, nearly one-quarter of unaccompanied youth reported that they receive medical care directly or through referrals from such programs. Despite the lack of attention to health care, homeless youth utilize and depend on such services being readily available. Studies show that if such programs are available, they are utilized. Homeless youth appear to access care most often for pregnancy, mental health issues, trauma, sexually transmitted infections, substance abuse, chronic conditions, and dental problems.

Homeless youth also report a reluctance to seek care for reasons such as difficulty navigating the health care system, limited clinic sites, lack of coordination among clinicians, specific hours for homeless youth, and long waitlists. They also report embarrassment, denial of any medical problems, and fear of a clinician's implicit and explicit biases.

Unaccompanied youth have various needs, including housing, education, vocational training, preventive health care, mental health care, screening for infectious disease, and substance and alcohol abuse services. Services that target this population rarely address all of them. The concept and principles of the "medical home" are essential to overcome such challenges, but this infrastructure is difficult to support in an outreach or emergency setting where such youth often present.

Once an unaccompanied youth is identified, the priority is to ensure that he or she is living in a safe environment. The youth should be assisted in making contacts that will enable access to safe housing. Resources specific for unaccompanied youth may not be available in all areas, but pediatricians need to be familiar with local service agencies, what they offer, and how to refer patients. Adolescent girls need to be able to access women's or domestic violence shelters (or family shelters if they are pregnant or have a child). Finding shelter for adolescent men may be especially challenging because they are often turned away from family shelters, and usually cannot stay in an adult shelter until they turn 18 years of age.

Whenever possible, unaccompanied youth should have access to routine preventive care, nutrition, and social services and, if uninsured, Medicaid. The youth will also need a thorough medical, developmental, and psychological history with a comprehensive physical examination. Particular attention must be paid to signs of abuse or trauma. They should be counseled on sexual health, offered screening for pregnancy and sexually transmitted infections, and provided with appropriate contraception (including access to plan B). Open-ended questions should be used to avoid assumptions about gender identity, sexual orientation, or sexual behaviors. Mental health screening is essential including assessment for mood disorders, PTSD, suicidality, and substance abuse disorders.

A safety plan should be developed for instances in which the safety of the youth is threatened, and a 24-hour emergency service should be identified. Case management, referrals for subspecialty care, psychological evaluation, and treatment should be available. If the youth resides in a shelter, then the precautions described earlier for infectious disease control should be taken. All visits to the clinic, even for a minor acute illness, are an opportunity to assess safety and high-risk behaviors, and to perform a thorough medical assessment. Continuity of care is a particular challenge among a transient population, but it is essential for effectiveness in the face of distrust and complex presenting problems. In an attempt to develop quality outcome measures through direct interviews with homeless youth, it was found that the vast majority identified continuity of care as important. They desired “. . . rapport with 1 clinician, and ‘not have to start all over again with repeating my story to someone else.’” In addition, they stated that respect was important to “. . . inform me, talk to me like a regular person instead of telling me what to do.”

Having a caring adult figure is developmentally protective for adolescents against hopelessness and emotional distress. Homeless adolescents often lack social connectedness, particularly to adults, because of histories of violence. Therefore, it is essential for clinicians to create a confidential, nonjudgmental “safe space” that consistently promotes autonomy and respect. Over time, this can foster resilience and trust around disclosing sensitive issues, such as sexuality, gender identity concerns, or trauma.

## LONG-TERM EFFECTS OF HOMELESSNESS ON WOMEN AND CHILDREN

Whether the experience of homelessness, in itself, has long-term effects on the health of a child is unknown. Although differences have been identified in the psychological and developmental characteristics of homeless children compared with housed poor children, it is not clear whether this difference is the result of events that occurred before or during homelessness. Nevertheless, it is reasonable to assume that providing needed educational, medical, and psychological services may mitigate toxic stress and limit the potential damaging effects of homelessness on the child.

It is important to keep in mind that many homeless families demonstrate an enormous amount of strength and resilience under adverse conditions and respond positively to the resources found in a medical home. In addition to identifying problems, clinicians can reinforce the strengths of the child and family, because they are crucial to helping them get through the crisis of being homeless.

## Chapter 79

### CHILDREN IN POVERTY

Renée R. Jenkins, MD; Earnestine Willis, MD, MPH;  
Sheryl E. Allen, MD, MS

Poverty, a social determinant of health, is a major contributor to adverse child health outcomes. The life-course perspective suggests that the effect of poverty during childhood has associated adverse outcomes into adult years. The negative effects of poverty and low income on health are seen across racial and ethnic groups; however, they disproportionately affect

minority children and result in significant racial and ethnic health disparities (Figure 79-1).

Family income, although not the only measure of poverty, is the measure most commonly used in defining poverty in the United States. Children living in poverty and low-income environments are not homogenous in their resources, either personally or materially. Family structure and dynamics, resilience, gender roles and expectations, education, duration and depth of poverty, health insurance, and access to health care are among the factors associating poverty with health status. It is necessary to recognize a child and family's assets, along with income-related risks, when prescribing interventions to promote positive health and developmental outcomes.

## DEFINING POVERTY AND LOW-INCOME STATUS

Poverty guidelines are issued each year by the US Department of Health and Human Services (HHS) for administrative use in determining family eligibility for certain federal- and state-administered programs. The same guidelines apply across the 48 contiguous states, with separate, slightly higher guidelines for Hawaii and Alaska. Since 1963, when the poverty thresholds were developed, 100% of the Federal Poverty Level (FPL) has been calculated by multiplying the cost of an economy food plan by 3 and adjusting for family size; however, the food share used to develop these thresholds does not represent today's consumption pattern for either the general population or the poverty population. Today, given the comparatively greater cost of housing and other basic needs, families are estimated to need an annual income of about twice the FPL to meet their basic requirements; hence, families at 200% of the FPL are identified as low-income or near-poor families. To view current federal poverty guidelines, go to [aspe.hhs.gov/poverty/15poverty.cfm](http://aspe.hhs.gov/poverty/15poverty.cfm).

**Figure 79-1** Across every racial and ethnic group, children's health varies according to family income. Data from National Survey of Children's Health, 2011–2012.

The percentage of children in poor families is almost twice that of adults aged 18 to 64 years and 2.5 times that of seniors 65 years and older. Young children are more likely to be poor or live in low-income conditions, as are children from racial and ethnic minority populations, children of parents who did not complete high school, and children with unemployed or part-time working parents. Contrary to the traditional stereotypes, 72% of children with at least one parent who works part-time or part-year and 48% of children living with married parents are low-income children.

Determination of poverty based only on annual household income suggests homogeneity of resources across families and denies the effect of other socioeconomic factors, such as assets, investments and liabilities, occupational status, neighborhood conditions, and other socioeconomic measures. All should be considered in determining contributory risk and protective factors for health and development outcomes. For racial and ethnic minorities, discrimination—at the institutional or personal level—may interact with poverty in a way that accounts for a more negative effect.

### WHY INCOME MATTERS: POVERTY AND CHILD HEALTH AND DEVELOPMENT

Children in poor and low-income families are at greater risk for adverse health outcomes from the perinatal period through adolescence. The negative effect on child health status occurs across the income gradients: the lower the income, the greater the effect. (See Table 79-1)

An analysis of poverty, overall health status, and activity limitation using the National Health Interview Status (NHIS) survey demonstrated, among children in poverty, a higher prevalence of chronic conditions, a higher incidence of low birth weight, and a lower percentage of mothers rating their child's health as excellent or very good. Measures of unmet mental health needs also disproportionately affected poor children. Disadvantaged mothers experience depression well beyond the postpartum period. Studies have shown that infants of depressed mothers are at risk for multiple developmental and medical problems. If treated, the mothers' symptoms improve, as do their perception of their child's behavior. Furthermore, mothers of poor children were more likely to perceive their child as being progressively limited over time because of a chronic condition when compared with nonpoor children. This finding points to the potentially enhanced benefit of early intervention and treatment for poor children with chronic conditions.

Morris and colleagues proposed a conceptual framework to explain the vulnerability of child health and development in poor and low-income families. They cited 2 mechanisms: effect of family stress and parenting practices, and inability to invest material (eg, food, housing) and nonmonetary (eg, time) resources. The family stress model proposes that instability of income raises parental stress (eg, hardships such as utility shutoffs, missed rent/mortgage payments,

unstable housing, no primary care physician, inconsistent child care arrangements) and results in a more punitive and inconsistent style of parenting. The inadequate resource model aligns with findings of poorer educational outcomes for children without cognitively stimulating home environments, sufficient food, and availability of books.

Children in families that experience food hardship or housing insecurity are also more likely to have health problems than other children.

In 2000, food insecurity was present in 10.5% of households and increased to 14.9% (17.9 million) of American households by 2011 because of lack of money and other resources for food at some time during the year.

### RESILIENCE

Resilience is defined as “exhibiting a better-than-expected outcome in the face of adversity.”

The concept of resilience is useful in explaining variations among health and educational outcomes of children in low-income families. Families living in poverty are described as resilient when their beliefs about the social and/or spiritual world nourish them, when they know how to take steps to control their destiny, and when they are good at seeking, receiving, and giving support and building interconnectedness. Examples of resilience in surveys show that low-income parents who rate their children as having excellent health are more likely to maintain more structured home environments around meals, follow safety practices, and practice routine dental hygiene. Family resiliency is fostered through individual (eg, belief system, effective coping skills), family (eg, family cohesion, supportive parent-child interaction), and community (eg, adequate housing, access to quality child care and schools) protective factors for at-risk families.

### OTHER PROTECTIVE FACTORS

#### Health Insurance

Fortunately, most poor and low-income children are covered by publicly funded health insurance (Medicaid or their state's Children Health Insurance Program [CHIP]); however, gaps persist between the numbers of children eligible and those enrolled. Immigrant children are less likely to be insured, with citizen children more likely than noncitizen children to have coverage.

Children with public health insurance are more likely to receive preventive health care in the primary care setting than uninsured children and have rates for well-child visits similar to children with private insurance. Uninsured children were 6 times more likely to have unmet medical needs and twice as likely to have unmet dental needs than children covered by Medicaid or CHIP. Being insured provides significant opportunity for children to have positive health outcomes. Unfortunately, as of 2011, 16% of poor and 16% of low-income children remain uninsured, with adolescents aged 12 to 17 years more likely to be uninsured than younger children. If fully implemented and sustained at the state and federal levels, the Affordable Care Act (ACA) has the potential to reduce the number of uninsured children in the United States by another 40% and the number of

uninsured parents by almost 50%. Using the Urban Institute's nationally recognized microsimulation models, researchers predict that 95% of all children in this nation will have coverage if ACA is fully implemented.

### Food Supplemental Programs

Food supplement programs, such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) (described later in this chapter), have been shown to reduce rates of low birth weight and iron deficiency.

Although there is a decline in iron deficiency prevalence among 1-year-old, black, and poor children, overall iron deficiency prevalence in US toddlers has persisted over the last 3 decades, and, despite the decline, it remains disproportionately elevated in certain high-risk groups: Hispanics, 1-year-olds, and overweight toddlers.

### Home Visitation

Home visitation programs, although often variable by content and outcome measure, have shown accumulating evidence that mothers with the fewest resources (ie, low income) often benefit most from the services. Home visiting has been shown to reduce rates of childhood injury, to reduce family welfare dependency, and to improve school readiness in at-risk families.

### Housing Subsidies

Increasingly, the federal government housing authority relies on portable housing subsidies, which provide lower-income households with vouchers to make housing more affordable in higher-quality neighborhoods. Housing subsidies have resulted in improved neighborhood safety and reduced exposure to violence, most successfully in black households, with limited effectiveness in Hispanic and white households.

### Quality Preschool

Early childhood interventions, such as Head Start, that address health and educational needs comprehensively have demonstrated positive health and behavioral outcomes. Head Start's mission acknowledges the influence of positive health care practices on multiple aspects of a child's development. Healthy preschoolers from low-income families have shown consistently to improve vocabulary, early writing, and early mathematics scores. Parents of children in Head Start are more likely to report having health insurance and regular dental care visits for their children. Reductions in mortality among children aged 5 to 9 years have been reported in examined long-term effects of Head Start since its introduction in the 1960s.

## ASSESSING CHILDREN IN THE OFFICE SETTING

The traditional social history obtained in the primary care office is not structured to assess basic needs of poor and low-income families. For these families the history should include more detailed information and encompass actual contributors to poor health, such as hunger and substandard housing. Other social history probes that can provide an assessment of a family's socioeconomic status include identification of social

stressors and support networks, recent change in environment, the ability to control events in one's life, and literacy. Physicians can use a tool like the IHELLP mnemonic described in Table 79-2 to assess these influences in the patient or family.

## CARE OF THE POOR AND LOW-INCOME CHILD

### Routine Health Supervision

Low-income children are at greater risk than their peers for overall poor health status indicators and special conditions such as overweight/obesity, asthma, vision and hearing problems, severe headaches, and ear infections (Table 79-2). In their day-to-day practices in medical homes, primary care physicians can promote optimal nutrition, growth, and physical health as part of health maintenance, including provision of immunizations and anticipatory guidance. Guidance regarding developmental and behavioral issues and concerns can help parents enhance their nurturing relationships with their children, especially those at risk because of limited material resources.

As part of daily practice to stimulate low-income children who have an increased vulnerability to learning and behavioral problems, primary care physicians can promote the "5 Rs" of early education.

- **Reading** together as a daily family activity (using the Reach Out and Read program, for example)
- **Rhyming**, playing, and cuddling together often
- **Routines** and regular times for meals, play, and sleeping, which help children know what they can expect and what is expected from them
- **Reward** with praise for everyday successes
- **Reciprocal** and nurturing relationships, which are the foundations of healthy child development

When anticipatory guidance reveals health-promoting behaviors, physicians can provide positive feedback and encouragement to continue and expand the practices. The Bright Futures selective screening criteria that affect low-income children include those for anemia, lead, tuberculosis, and dyslipidemia screening. Low-income children with environmental risk, including limited access to food, should be screened for anemia at the 18-month visit and 2- to 5-year annual visits in addition to the initial screen at 9 to 12 months of age. Children exposed to old housing, children who are refugees, and children in communities with identified lead exposure require lead screening. Immigrant children born in high-risk countries should be screened for tuberculosis, and physicians should be attentive to guidelines for dyslipidemia screening in overweight low-income children. Physicians can improve identification of children with developmental delays by integrating regular, systematic, developmental screening and surveillance into their practices. Children identified as having developmental delays and children at risk for delays can be referred to community-based services, such as early intervention programs (eg, Birth to 3), home visitation programs, Head Start, and special education programs available through public schools. An appropriate response to identified socioeconomic stressors is to offer potential problem-solving strategies, pose further

**Table 79-2****Examples of Potential Social History Questions (Using the “IHELLP” Mnemonic) to Address Basic Needs**

DOMAIN/AREA	EXAMPLES OF QUESTIONS
<b>INCOME</b>	
General	Do you ever have trouble making ends meet?
Food income	Do you ever have a time when you don't have enough to food? Do you have WIC? Food stamps?
<b>HOUSING</b>	
Housing	Is your housing ever a problem for you?
Utilities	Do you ever have trouble paying your electric/heat/telephone bill?
<b>EDUCATION</b>	
Appropriate education placement	How is your child doing in school? Is he/she getting the help to learn what he/she needs?
Early childhood program	Is your child in Head Start, preschool, or other early childhood enrichment?
<b>LEGAL STATUS</b>	
Immigration	Do you have questions about immigration status? Do you need help accessing benefits or services for your family?
<b>LITERACY</b>	
Child literacy	Do you read to your child every night?
Parent literacy	How happy are you with how you read?
<b>PERSONAL SAFETY</b>	
Domestic violence	Have you ever taken out a restraining order? Do you feel safe in your relationship?
General safety	Do you feel safe in your home? In your neighborhood?

questions for clarification, and offer referral sources, including the safety net programs described in the following text. Pediatricians can monitor children's participation and progress as a result of these referrals.

## SAFETY NET PROGRAMS

Safety net programs offer low-income families opportunities to become more economically stable. Pediatricians need to become knowledgeable about the basics of such programs, to advocate for them and consider them as a resource for low-income and poor families in their care. Safety net programs may be sponsored by nonprofit or faith-based organizations or local, state, or federal government. Several federally funded programs (Temporary Assistance for Needy Families; Earned Income Tax Credit; Child Support; Child Care Subsidies; WIC; National School Nutrition Programs; and Food Stamps) are discussed in the following text. Medicaid and CHIP are described in Chapter 1, Health Care Delivery System.

Not detailed in this chapter are several other safety net programs beneficial to economically disadvantaged populations. Pediatricians should familiarize themselves with those programs, which include Supplemental Security Income, Social Security Disability Insurance, Unemployment Insurance, Early Head Start, and Head Start. Many low-income families depend on the National School Lunch Program and School Breakfast Program to provide food for their school-aged children; these programs provide free and reduced-priced nutritionally balanced meals

to eligible children living below 130% and below 185% of the federal poverty threshold, respectively, for the families to meet the daily food requirements.

## Temporary Assistance for Needy Families

In 1996, welfare reform legislation replaced the existing welfare programs (Aid to Families with Dependent Children, Job Opportunities and Basic Skills Training, and Emergency Assistance) with Temporary Assistance for Needy Families (TANF). The Personal Responsibility and Work Opportunity Reconciliation Act released the federal government from responsibility to provide direct financial support based on entitlement, and instead provided funds for administration of public assistance at the state level. To receive TANF, adults with dependent children must pursue job opportunities and training. After the benefits begin, the adult has up to 60 months of support, which can be terminated if the state determines the individual is capable of obtaining an entry-level position. Of the 12 million people who receive TANF, most are single mothers.

## Earned Income Tax Credit

The Earned Income Tax Credit (EITC) is a refundable income tax credit for low- to moderate-income working individuals and families, usually for those whose annual income is between \$35,000 and \$48,000. The structure of the federal EITC program and the 24 state-level EITCs allows families to receive money back, based on income, marital status, and number of children. To qualify, an individual must meet certain

**Figure 79-2** Share of SNAP households with children by type of income. (Reprinted with permission from Testimony of Robert Greenstein, President, Center on Budget and Policy Priorities Before the House Committee on Agriculture. February 25, 2015. Available at: [www.cbpp.org/testimony-of-robert-greenstein-president-center-on-budget-and-policy-priorities-before-the-house](http://www.cbpp.org/testimony-of-robert-greenstein-president-center-on-budget-and-policy-priorities-before-the-house). Accessed October 5, 2015.)

requirements and file a tax return, even if he does not owe any taxes. Congress approved this tax credit legislation in 1975 with the goal of rewarding and encouraging working, in addition to helping families offset the burden of Social Security taxes. Many families use EITC refunds to pay for necessities, make repairs to homes or vehicles, or continue with higher education and training.

### Child Support

Child support enforcement occurs at the state level and involves the collection of court-ordered child support payments. More than 60% of child support collected each year occurs by the direct withholding of money from the court-ordered noncustodial parent. If child support monies are not collected from the noncustodial parent, serious penalties can occur, including the retention of federal and state tax refunds, liens on property, freezing of bank accounts, and suspension of driver, occupational, or operation licenses.

### Child Care Subsidy

The Child Care and Development Fund (CCDF) is the key resource that the federal government provides for funding child care subsidies to support work among low-income families. It is administered by the Administration for Children and Families (ACF) in the Department of Health and Human Services. Annually, each state has an allocation of funds for child care subsidies consisting of separate mandatory, matching, and discretionary funds. Child care subsidies provided through CCDF and associated state funding assist nearly 1 million families and 1.6 million children in an average month.

### Supplemental Nutrition Assistance Program (Food Stamps)

The national Supplemental Nutrition Assistance Program (SNAP), historically known as the Food Stamps program, provides more than 46 million poor and low-income Americans with a mechanism to acquire nutritionally adequate food. Since 2004, all states use an Electronic Benefit Transfer (debit card) for all

food stamp benefits. Eligibility for food stamps is based on the following rules: (1) A household's gross monthly income must be at or below 130% of the FPL; and (2) household and vehicle assets must be below \$2,000 to \$3,250 (based on different circumstances), consistent with TANF rules. There is some variability, however, in how states handle the vehicle assets: some exclude the entire value of vehicles; some count the value of vehicles; some exclude the value of 1 vehicle per household. Each state designates the application process for food stamps, although most have a centralized location, and most require able-bodied adults between 16 to 60 years of age to register for work, accept suitable employment, and take part in an employment and training program to receive the nutrition benefit. Figure 79-2 illustrates the proportion of households with children receiving food stamps by working status from 1990 to 2013.

### Special Supplemental Nutrition Program for Women, Infants, and Children

The Special Supplemental Nutrition Program for Women, Infants, and Children is a federally funded program administered by the states for low-income pregnant women, breastfeeding mothers, and infants and children up to the age of 5 years. Families receive monthly checks or vouchers redeemable for baby formula, infant cereal, iron-fortified adult cereal, milk, vitamin C-rich fresh fruit, fruit and/or vegetable juices, eggs, cheese, and certain other foods for their consumption. Soy-based beverages, tofu, baby foods, whole-wheat bread, and other whole-grain options were recently added to the program. A few state agencies distribute WIC foods through warehouses or deliver the food to participants' homes. In addition to making nutritious foods more accessible to families, WIC provides nutrition education, breastfeeding support, health and social service referral, and referrals for health care. The WIC eligible food list is available at [www.fns.usda.gov/wic/benefitsandservices/foodpkgregs.HTM#JUICE\\_\(Women\\_and\\_Children\)](http://www.fns.usda.gov/wic/benefitsandservices/foodpkgregs.HTM#JUICE_(Women_and_Children)).

The nutritional foods supplied by WIC vouchers provide families with access to a balanced diet of specific items.

A study in 2008 found that WIC families who had access to a weekly voucher for fresh foods from either a farmers' market or a supermarket were more likely to increase their daily intake of fruits and vegetables and maintain that increase. Beginning in 2009, WIC participants began receiving vouchers for farmers' market and supermarket use, covering fresh, frozen, and canned fruits and vegetables (minus potatoes and foods provided by their state commodity supplement program). WIC also covers many unprepared foods, whole grains, and brown rice, all of which are high in either protein, calcium, iron, vitamin A, or vitamin C. Additional foods are available for women who are breastfeeding, until their infant turns 12 months old. If a woman chooses not to breastfeed, infant formula is included with the WIC program vouchers, along with infant solid foods.

The medical benefits of providing foods with strong nutritional value include higher birth weights, lower infant mortality rates, lower numbers of preterm births, and a higher rate of preventive health service use. Women enrolled in WIC tend to have healthier pregnancies and deliveries. WIC mothers deliver fewer preterm infants than women not enrolled in WIC. In fact, these women generally tend to have babies of healthy birth weight. Khanani and colleagues demonstrated that WIC participation significantly reduced the disparity in infant mortality rates between African Americans and whites compared with non-WIC participants.

In addition to food vouchers, the WIC program provides some nutritionally at-risk women and children with social service referrals.

## LIMITATIONS OF SAFETY NET PROGRAMS

Many of the safety net programs summarized in the previous text do not coordinate or integrate with each other. For example, as wages increase to elevate a family's income, the family may lose benefits such as child care subsidy and have, effectively, less cash than before the wage increase. The dilemma could be remedied by allowing families to phase out government-sponsored benefits such as EITC, child care, or food stamps. This phasing out of benefits would result in a more gradual loss of benefits to prevent families from slipping back into poverty. To minimize the poverty burden on children and families, policymakers must examine the consequences of lack of coordination of programs that were originally designed to lift families out of poverty and the service gaps created by interstate variability in benefits.

## PUBLIC POLICY OPTIONS FOR CHILD ADVOCATES

Most low-income children have parents who work at low-wage jobs, bringing in insufficient income to pay for basic family expenses. Limitations in social and political power result from low-income status. In addition, work support benefits are inadequate and difficult to access. Physicians can collaborate with policymakers to reframe social and health policies to support low-income families and promote the healthy

growth and development of their children. Examples of such policy reframes might include a reduction or elimination of asset tests for major means-tested benefit programs. Many states have chosen to reduce or eliminate asset tests in work support programs as a means to assist recipients in achieving self-sufficiency. Other states, such as California, Colorado, and Illinois, have restructured their programs by increasing the amount of cash resources and exemptions allowed for certain forms of assets. Physicians also have opportunities to affect their communities through American Academy of Pediatrics (AAP) grant programs, educational resources, and federal and state advocacy strategies. Grants for projects that increase access to health care, preventive health care, and service coordination are just a few of the services funded through the Coordinated Approach to Child Health (CATCH) and Healthy Tomorrows programs. The AAP Council on Community Pediatrics is a source of ongoing direction to physicians about poverty and child health.

In addition, collaboration between physicians and lawyers can ensure that the basic needs of families are met. A national model called "medical-legal partnerships" has emerged as an effective intervention to ensure that low-income families benefit from government-sponsored programs for which they are eligible. In this model, a lawyer on site at a medical practice offers families assistance in advocating for legal and social services, especially those with outcomes that affect health status, such as housing and special education programs. Box 79-1 summarizes public policy

### BOX 79-1 Public Policy Options to Mitigate Economic Insecurity

- Phase out rather than abruptly terminating supplementation programs ("falling off the cliff")
- Promote financial and health literacy
- Invest in early childhood education
- Eliminate asset tests in means-tested programs
- Support Temporary Assistance for Needy Families (TANF) with focus on family-friendly workplaces
- Expand home visitation
- Integrate quality programs across education, workforce, health, housing, neighborhoods
- Develop asset-building programs
- Expand family leave policies
- Expand safety net programs to a greater share of eligible children
- Provide comprehensive health insurance coverage
- Ensure that working at minimum wage covers a family's basic expenses
- Invest in safe neighborhoods
- Coordinate programs for children applying for or receiving multiple government-sponsored benefits (eg, offer a universal application)

Adapted from Kaplan GA. The Poor Pay More: Poverty's High Cost to Health. September 2009. Available at: [hdl.handle.net/2027.42/65007](http://hdl.handle.net/2027.42/65007). Accessed January 7, 2015.

options that various experts have suggested to mitigate economic insecurity for children of low-income families.

## SUMMARY

Although children living in poverty and low-income environments are at greater risk than their peers for adverse health and educational outcomes, a number of home, clinic, school, community, and government interventions have been shown to mitigate these risks successfully. Primary care physicians have opportunities to nurture resilience in low-income children and families, identify and address the health problems they face, and connect them to community services and safety net programs that are likely to improve their health and educational outcomes. Physicians can also serve as advocates for enactment of public policies that support children in low-income environments.

## Chapter 80

# PERINATAL PREVENTIVE CARE: FETAL ASSESSMENT

*E. Rebecca Pschirrer, MD, MPH; George A. Little, MD*

Pediatricians, as primary care physicians and as subspecialist neonatologists, consult and work collaboratively with obstetric providers in preconception counseling, fetal risk identification, and peripartum decisions. Years ago, pediatricians first saw their newborn patients in the nursery, but only after the events of pregnancy and delivery; today their initial interaction with the pregnant woman may be during a prenatal pediatric visit. In addition, pediatricians assume primary responsibility for resuscitation, stabilization, and ongoing care of the neonate from the moment of birth. Knowledge about fetal health includes appreciation of the interaction of the fetus with the mother, her partner, health professionals, and society. Many examples exist of the capacity for fetal medicine, as part of preconception and prenatal care, to prevent or treat problems and improve outcomes.

Parents and professionals have good reason to be concerned about the immediate and long-term effects of agents or processes on the fetus. Infections such as rubella can result in the loss of the fetus or in multisystem disease. The magnitude and seriousness of manifestations of maternal alcohol consumption, tobacco use, or substance abuse during pregnancy may be evident in the infant's physical appearance or behavior in the neonatal period and throughout the child's life course. Furthermore, problems may not appear until a subsequent generation. The effects of diethylstilbestrol, once given to mothers to reduce the risk of pregnancy complication or abortion, for threatened abortion, were not recognized until the appearance of clear cell carcinoma of the vagina in female offspring 10 to 20 years later.

Growth and development are as much a key to fetal medicine as they are to pediatrics, of which study of the fetus is merely the first phase. Human growth and development must be regarded as a continuum that begins with conception (Figure 80-1). This chapter outlines some of the normal physical and interactive aspects of fetal existence, then discusses selected pathophysiologic states that may adversely affect that existence.

## MATERNAL CONDITIONS THAT AFFECT THE FETUS AND NEWBORN

Many authorities have pointed to socioeconomic status and social environment as causes of fetal risk. Delineation of specific influences is difficult, but poverty is undoubtedly important, as are nutrition and hygiene. Intrauterine infection is more frequent in mothers of lower socioeconomic status. Emotional influences on fetal loss have been discussed; in addition, the possibility that medical or socioeconomic deprivation contributes cannot be discounted. Knowledge

of a patient's race, ethnicity, and language and communication needs can assist in the provision of patient-centered care, facilitate appropriate risk assessments, and improve perinatal outcomes. Socioeconomic status, immigration, and health literacy may further moderate the effect of race, ethnicity, and language. Quality maternity and perinatal care can be influenced by a provider's identification and understanding of the cultural beliefs and experiences of the pregnant woman and her family, and by the expression and understanding of health care needs communicated by patients.

The risk for adult health disorders, particularly obesity and metabolic syndrome, can be markedly influenced by early life events, such as maternal preexisting and pregnancy-related health conditions and environmental exposures. These pregestational and gestational factors affect both prenatal and neonatal growth trajectories. Alterations in embryonic and fetal nutrition as well as endocrine status during gestation can result in developmental adaptations that produce permanent structural, physiologic, metabolic, and epigenetic changes, thereby predisposing an individual to adult cardiovascular, metabolic, and endocrine diseases, particularly metabolic syndrome.

## Maternal Nutrition

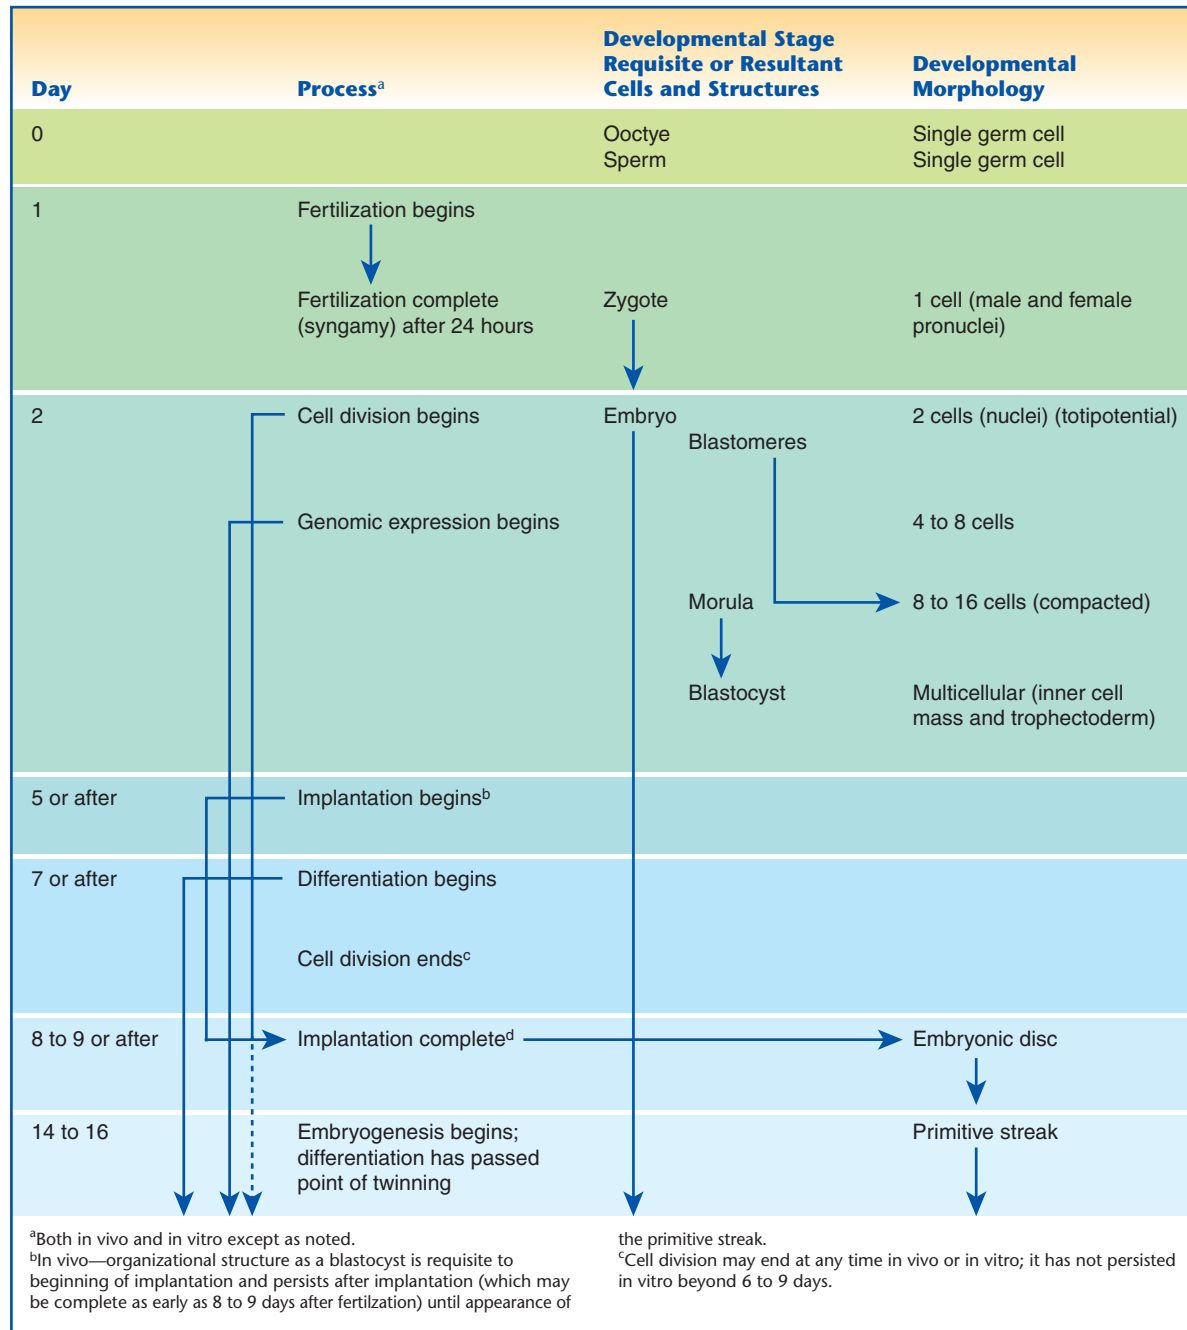

Maternal nutritional disorders represent a definite risk to the fetus, including situations in which gross deprivation is not apparent. The supply of substrate to the fetus for growth originates with the maternal circulation and passes through an interface with fetal tissue at the placenta. Placental insufficiency can result in intrauterine growth restriction (IUGR) that is not of maternal origin. The relationship between maternal and fetal nutrition is complex. Maternal dietary changes usually do not directly or rapidly influence fetal well-being; thus, the positive or negative effects of changes in maternal nutrition are not easily recognized. Maternal weight is an important concern.

Traditionally, 2 types of nutritional deficiency have been conceptualized: general caloric or energy-related deficiency states and specific deficiencies. Deprivation of maternal caloric intake to the point at which fetal growth is markedly impaired also may be associated with specific deficiencies. If maternal caloric deprivation is severe, then fertility is decreased.

Women whose prepregnancy weight is below standard for height tend to have babies whose weight is less than expected. Women who are obese tend to have heavier babies. Problems such as hyperemesis gravidarum can result in fetal caloric deprivation. The mother's expression of eating disorders that often start during late childhood and adolescence is a possible fetal risk.

Specific deficiencies are well recognized; their risk to the fetus can be reduced through public health and individual clinical interventions. Vitamin deficiencies are of interest, and problems such as congenital beriberi (lack of thiamine) and infant calcium disorders (lack of maternal vitamin D) are of historical interest and decreasing incidence. Studies have

### Early In Vivo and In Vitro Human Development Process

**Figure 80-1** Fetal and child development begins with fertilization and is similar in vivo and in vitro for 6 to 9 days. (From American College of Obstetricians and Gynecologists. *Using preimplantation embryos for research*. ACOG Committee Opinion No. 347. Obstet Gynecol. 2006;108:1305–1317. Used by permission.)

confirmed that neural tube defects can be reduced by consuming folic acid, with the best protection achieved when 0.4 mg is ingested from at least 1 month before conception through the first month of pregnancy.

Minerals are a major concern in pregnancy. Iodine deficiency is said to be the most common cause of preventable mental deficiency in the world; treatment

during pregnancy protects the fetal brain, with later treatment being much less beneficial to neurologic status. Zinc deficiency may also be associated with anomalies. Maternal anemia caused by reduced availability of iron is well known; the fetus and infant, as a result, can have low iron stores, making the infant susceptible to iron deficiency if intake after birth is inadequate.

## Environmental Exposures

Adverse reproductive and developmental effects have been linked to environmental exposures. Vulnerability to toxic insult varies with the rate of cell division and with the developmental state of the exposed tissues; rapidly dividing cells, such as spermatocytes, neural stem cells, and embryonic cells, will be especially susceptible. Adverse birth outcomes include preterm birth and low birth weight (IUGR), congenital malformations, spontaneous pregnancy losses, and neurodevelopmental impairments. Environmental factors, such as radiation, chemicals, and drugs, affect people of all socioeconomic classes. A woman's preconception or prenatal history should include review of history of alcohol and smoking as well as secondhand smoke exposure, illicit substance use, and other environmental exposures. These environmental toxicant exposures include mercury intake through fish consumption; well-water nitrate exposures; exposures to chemical, physical, and/or biologic hazards in the workplace or community; and lead and other toxicant exposures in the home. It is important to be aware that males are also vulnerable to environmental toxin exposures. Male-linked factors (referred to as *male-mediated teratogens*) that have been identified as having the potential to cause damage to offspring include cocaine, alcohol, some pesticides and solvents, such as dibromochloropropane and trichloroethylene, and heavy metals such as lead and mercury. Reviewing exposure and risk factors for potential exposure is important, particularly for exposure to mercury, lead, pesticides, and endocrine disruptors, such as phthalates, bisphenol A, and polybrominated diethyl ethers. There are many excellent resources available regarding environmental exposures, which are listed at the end of the chapter. Radiation exposure in mammals causes fetal death, growth retardation, and congenital malformation, with the central nervous system (CNS) commonly affected. The relationship between embryonic or fetal irradiation and carcinogenesis is unclear. Effects are both dose and rate related. Death during the preimplantation period, malformation during early organogenesis, and cell deletion and hypoplasia during fetal life form a general pattern in animal studies. Guidelines exist for limiting radiation to the embryo and fetus during occupational exposure or elective diagnostic techniques; however, dilemmas often arise as a result of lack of foreknowledge about pregnancy, nonelective medical evaluations, and emotional factors. When necessary, a radiation physicist should be consulted.

Air pollution can originate from multiple sources, such as car exhaust, power plants, factories, fires, and fumes from solvents. Of the many chemical components that constitute air pollution, 4 of the most dangerous pollutants are sulfur dioxide, carbon monoxide, nitrogen oxides, and particulate matter. Exposure to air pollution early in pregnancy can affect fetal development. Similarly, exposure to pesticides (organophosphates) and herbicides through contact with contaminated air, food, and ground water can lead to IUGR and anomalies, such as limb reduction deformities and urogenital and musculoskeletal defects. Neurotoxicity can result from prenatal and postnatal exposure to lead and methylmercury, leading to neurodevelopmental and

cognitive impairments, cerebral palsy, sensory deficits (blindness, deafness), and deficits in attention, fine motor function, language, visual-spatial abilities, and memory.

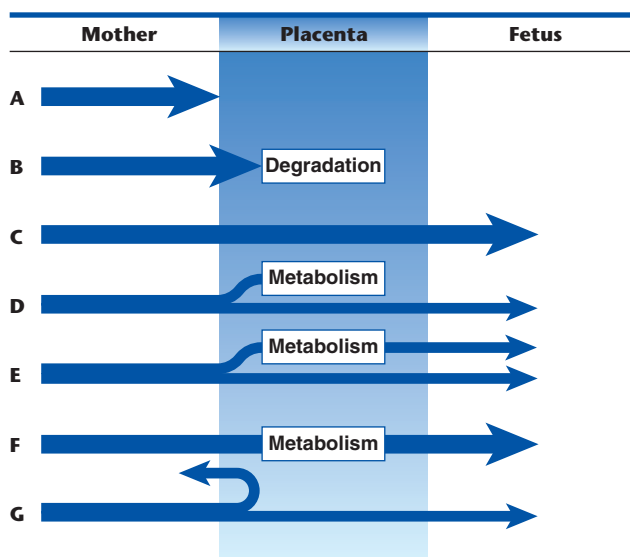

Chemicals in the environment are of natural and synthetic origin. Certain substances, such as pesticides and mercury, have been the focus of attention, although more study of other potential environmental toxins is needed. Many agents are potentially more toxic to the embryo, fetus, and neonate than to older children and adults. Perchlorate, both a naturally occurring and a human-made contaminant increasingly found in groundwater, surface water, and soil, is another environmental toxin of increasing concern because of its interference with thyroid uptake of iodide and potential to affect child health and development. Lead exposure during pregnancy, at both low and high levels, has been associated with adverse fetal and neonatal outcome. Appropriate maternal calcium intake may decrease fetal lead exposure, resulting from decreased mobilization of stored lead in maternal bone.

Mercury exposure is a major issue in environmental health, in large part because of its toxicity to the brain, especially the more susceptible fetal brain. Mercury is common in the environment in small amounts and occurs in 3 forms: the metallic element, inorganic salts, and organic compounds. Predatory fish are the primary exposure, and local fish advisory bans are available from the US Environmental Protection Agency. Women planning pregnancy, women who are pregnant or breastfeeding, and children younger than 15 years have been advised to avoid eating swordfish or shark and to limit the amount of tuna eaten. Updates on information regarding the safety of fish and shellfish, as well as resources for local health departments, may be found through the US Environmental Protection Agency. Research has shown variable amounts of mercury during testing of different brands of tuna. Thimerosal, a mercury-containing preservative used in some vaccines, has been the subject of concern and controversy, resulting in its no longer being used in vaccines despite the lack of evidence of causality. (See Chapter 20, Immunizations.)

## Drugs and Other Substances

Drug use during pregnancy is epidemic and may be on the rise. Physicians must be concerned about all types of drug use: legitimate (nonprescription and prescription), social, illegal, and abusive. All health care professionals, especially the primary care physician, should recognize that the concept of the placenta as an effective toxic substance barrier between maternal and fetal circulation has been discarded.

The maternal-fetal pharmacologic mechanism is complex, with the placenta serving as an organ of exchange (Figure 80-2). Placental diffusing capability or permeability of the simple variety operates for many substances; energy-utilizing transport is also important. Drugs in the maternal circulation should be assumed to cross the placenta and should be evaluated for potential teratogenesis. The risk to the fetus depends on several factors, including concentration of the substance, length of exposure, and when exposure occurs during gestation.

**Figure 80-2** Maternal-fetal transport patterns and the role of the placenta, a fetal organ with active metabolic activity. **A**, Placental barrier with minimal uptake or transfer (eg, succinylcholine, highly charged quaternary compounds). **B**, Active placental uptake and degradation without transfer as seen with insulin. **C**, Placental uptake and transfer without significant change as with bilirubin. **D**, Placenta actively involved in uptake, partial use, and transfer (oxygen, glucose, amino acids, free fatty acids). **E**, Uptake, partial metabolism, and transfer (cyclosporine). **F**, Placenta actively modifies during transfer (25-hydroxyvitamin D<sub>3</sub>). **G**, Carrier-coupled uptake occurs with release of ligand to the fetus and regeneration of carrier on the maternal side (transferrin-iron). (Adapted from Pridjian G. *Feto-maternal interactions: placental physiology and its role as a go-between*. In: Avery GB, Fletcher MA, MacDonald MG, eds. *Avery's Neonatology: Pathophysiology and Management in the Newborn*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999. Reprinted by permission.)

Therapeutic agents, both prescribed and nonprescribed, may be taken before pregnancy is recognized, thereby placing the products of conception at risk during the period of organogenesis in early gestation. An important benefit of preconception or interconception care is the opportunity to identify medication uses that are necessary, such as anticonvulsants, or desirable, such as nonnarcotic analgesics, and to monitor or modify exposure. Examples of problems include fetal hydantoin syndrome and the potential effects on the mother and fetus of aspirin, including clotting abnormalities and disruption of prostaglandin synthesis.

Many of the therapeutic agents indicated during the course of pregnancy and delivery require judicious use because of known and potential risks. Antimicrobial therapy is often necessary when treating maternal conditions, such as urinary tract or gynecologic infections, but must be used with the knowledge that well-recognized fetal problems can result, such as bone and dental dysplasias associated with fetal tetracycline exposure and the potential hearing loss of fetal

aminoglycoside toxicity. Cardiovascular medications that cross the placenta readily, such as digitalis, can be used to treat the fetus or can cause fetal problems. Selective serotonin reuptake inhibitors (SSRIs), such as commonly used antidepressants, have been shown to cause mild neonatal abstinence syndrome. A report has been issued of an increased rate of persistent pulmonary hypertension of the newborn among infants exposed to SSRIs late in pregnancy; however, the absolute risk is likely to be less than 1%. Furthermore, no significant relationship has been found between SSRI exposure and stillbirth, neonatal death, or post-neonatal death.

Pediatricians need to know the effects of obstetric drugs on the fetus, including narcotics, oxytocin, and magnesium sulfate, which can cause depressed respiration, hyperbilirubinemia, and hypotonia, respectively. Socially used and abused drugs are very well known to pediatricians for their deleterious effect on the fetus, newborn, child, and adult. Mothers who smoke have babies who are smaller than those of non-smokers by an average of 200 g. Varied active agents in smoke, such as carbon monoxide and nicotine, have physiologic effects. Evidence suggests that antenatal exposure to environmental tobacco smoke affects early childhood cognitive development. Infants exposed to tobacco smoke prenatally and postnatally are at increased risk for childhood asthma, respiratory infections, otitis media, and sudden infant death syndrome, as well as later behavioral problems and increased rates of adolescent smoking. The clear medical consensus is that smoking is a health hazard for the fetus and newborn. Maternal alcohol consumption is associated with fetal alcohol syndrome and should be discouraged during pregnancy in all trimesters, although demonstrating deleterious effects is difficult when small amounts are consumed.

Addictive drug use during pregnancy creates major medical and societal problems. Many, if not most, users have lifestyles that include factors such as poor nutrition or lack of prenatal care that present significant background risk regardless of the addictive agent. Heroin is known to reach the fetus soon after maternal use, with intrauterine dependency and withdrawal recognized. Treatment programs that use methadone or buprenorphine are preferable alternatives to continued illicit opioid abuse, although neonatal withdrawal requires appropriate evaluation and management. Outcomes of women and infants in treatment programs are significantly better than those of women not enrolled in treatment.

Cocaine is considered to be responsible, directly or indirectly, for many admissions to neonatal intensive care units. Cocaine use can result in problems such as placental abruption that compromise the fetal and neonatal cardiovascular and neurologic systems. Investigative efforts to characterize and quantify long-term neurodevelopmental effects are ongoing. (See Chapter 104, Prenatal Drug Use: Neonatal Effects and the Drug Withdrawal Syndrome.)

Identification of environmental and lifestyle risks relies largely on the maternal medical history. Paternal history is also important to investigate. When specific factors such as radiation or chemical exposure are

detected, assessment of fetal well-being, especially its growth and morphology, may be helpful. In many situations, however, decisions to continue or terminate pregnancy are made based on possible fetal effects, involve parental emotions and values, and require compassionate, nondirective counseling in addition to the presentation of available scientific knowledge.

### Dental Health

The relationship between periodontal disease and pregnancy outcome is controversial. Some studies have shown women with periodontal disease are at increased risk for adverse perinatal events compared to women without periodontal disease, whereas others have shown no relationship. The increasing popularity of oral jewelry, including lip and tongue piercing, has been associated with higher incidence of periodontal disease. Women who are planning a pregnancy should pursue regular dental care, with treatment of poor dentition and gingivitis.

### Maternal Reproductive Capability and Health

Certain maternal factors result in fetal risk. Pregnancy can produce physiologic changes in the mother that may complicate preexisting maternal conditions, thereby jeopardizing the fetus. For example, mothers who have asymptomatic cardiac disease may decompensate when they become pregnant.

Maternal biologic factors, such as age, weight, height, race, parity, and previous obstetric history, directly affect fetal risk. Perinatal mortality increases at the extremes of maternal age; the relative risk for stillbirth increases with maternal age, regardless of medical comorbidity, parity, or race and ethnicity. One large observational study determined the lowest risk to be in the 16- to 19-year range. However, such observations should not be taken to encourage adolescent pregnancies; pregnancy in those younger than 16 years has definite associated risks, and pregnancy throughout the teenage years is associated with medical and social morbidity. Newborn weight and height are related to maternal nutrition, socioeconomic status, and other variables, which may jeopardize the fetus by increasing the incidence of prematurity or intrapartum complications. Race is a complex factor that includes socioeconomic considerations; some congenital anomalies and medical conditions may be racially predisposed. Congenital maternal reproductive tract abnormalities are often associated with spontaneous abortion and with prematurity. Cervical insufficiency occurs in 1 in 500 to 600 pregnancies and can result in premature delivery. The interval between pregnancies is an important contributor to the risk for low birth weight.

Maternal medical disorders carry a significant risk to both fetus and mother. Cyanotic congenital heart disease in a mother is clearly related to fetal problems, including IUGR and prematurity. Termination of pregnancy should be considered if maternal cardiac decompensation later in the pregnancy is anticipated. Asthma can threaten mother and fetus but is commonly well controlled with medication. Tuberculosis demands aggressive management of maternal disease with attention to potential fetal exposure to drugs. Pregnancy

in women who have cystic fibrosis presents the fetus with a variety of medications, maternal pulmonary insufficiency, and possible nutritional deficiency.

Preexisting and new-onset renal disease can complicate pregnancy. Fetal risk increases markedly in the presence of maternal proteinuria, impaired renal function, and hypertension. Hypertension can result in placental changes leading to IUGR. Adverse fetal outcome from urinary tract infection relates primarily to the risk for premature birth. Successful pregnancy is possible in women with kidney transplants, with the best outcomes seen among women who have stable renal function, time since transplantation of at least 2 years, and no evidence of rejection. Some risks are associated with exposure to immunosuppressants, but they do not prohibit a good outcome.

Maternal hematologic problems are common. In developing countries, anemia has been demonstrated to correlate with low birth weight; the effect of moderate maternal iron deficiency on the fetus is unclear. Some hemoglobinopathies can profoundly increase fetal mortality and morbidity as a result of either maternal health status or fetal disease. Pregnant patients who have sickle cell disease require close attention. Immune sensitization problems (Rh, ABO) are discussed later in this chapter and in Chapter 93, Maternal Medical History.

Maternal metabolic disorders can be significant for the fetus. The interaction of mother and fetus seems limitless: Compounds are metabolized actively on both sides of the placenta; fetal organogenesis and development may be affected; and fetal end organs may respond to maternal abnormalities. Two conditions, diabetes and thyroid disorder, deserve special mention.

Diabetes in pregnancy causes a myriad of fetal complications, including stillbirth, increased frequency of congenital anomalies, macrosomia (a large-for-gestational-age state characterized by an increase in fat but not in total body water), and conversely, growth restriction in a small number of infants. Evidence suggests that fetal pulmonary and neurologic maturity may be delayed in these pregnancies. In addition, obstetric problems, including preeclampsia, hydramnios, and intrapartum complications, resulting from excessive size, increase risk further. Glucose is a primary metabolite of the fetus. Pregnancies complicated by diabetes may cause fluctuations in maternal-fetal glucose, with resultant fetal hyperinsulinism and hypoglycemia. The increase in pancreatic islet tissue leads to fetal hyperinsulinism, which may be associated with a growth hormone effect that results in macrosomia. Severe maternal diabetes, especially when complicated by prepregnancy vascular disease, may result in small fetuses rather than macrosomia because of placental insufficiency and fetal nutritional deficit. Close control of maternal diabetes results in a better overall perinatal outcome.

Maternal thyroid disease is much less common than diabetes but also has profound fetal effects. Fetal thyroid function appears by 12 weeks' (12<sup>0</sup>/12<sup>6</sup>/) gestation; thyroxine and triiodothyronine can cross the placenta in small amounts in either direction. Classic cretinism, a reflection of maternal and fetal hypothyroidism, includes obvious fetal neurodevelopmental

problems and is a result of endemic iodine deficiency or autoimmune maternal thyroiditis. Evidence is accumulating that maternal hypothyroidism, even when subclinical, interferes with normal fetal brain development and may be prevented by maternal screening and treatment. Spontaneous loss, stillbirths, anomalies, and prematurity can be associated with hypothyroidism. Increases in maternal thyroid replacement hormone are generally necessary during pregnancy. Hyperthyroidism, when untreated, increases fetal loss. Its treatment, however, carries a definite risk to the fetus because antithyroid drugs may affect the fetal thyroid, and surgical intervention carries an operative risk to fetus and mother. Postoperative treatment with thyroid replacement therapy may minimize fetal complications.

Although seizure disorders are common, their course during pregnancy is difficult to predict with certainty. The status of approximately one-half of those affected is unchanged, and of the remaining number, one-half improve and one-half become worse. Status epilepticus is an emergency for the mother and fetus. Some anticonvulsants, such as trimethadione and valproic acid, are clearly teratogenic. Carbamazepine is associated with an increased risk for neural tube defect. Phenytoin has been linked with a fetal hydantoin syndrome, although the actual incidence is much debated. Phenobarbital, carbamazepine, phenytoin, and other medications have a broad-based effect on fetal enzymatic systems; they are associated with vitamin K-dependent coagulation factor deficiency in neonates. Many perinatologists suggest additional supplementation of vitamin K in the last month of pregnancy. Women who have epilepsy have an approximately 1 in 40 chance that their children will develop the same condition.

Seizures that seem *de novo* in pregnancy must be thoroughly evaluated. Eclampsia usually produces other signs and symptoms and is associated with a high incidence of fetal and neonatal complications.

Maternal emotional status presents too complex a relationship with physical and familial status to be used as a specific fetal risk factor in most situations. Whether maternal emotional illness not related to pregnancy can affect the fetus directly is unclear. Pregnancy-caused or pregnancy-aggravated crises leading to abortion, drug abuse, or poor maternal nutrition generate obvious fetal consequences.

### Placenta and Membrane Disorders

The placenta and associated membranes are tissues on which the fetus depends for respiration, nutrition, protection, and other functions. Manifestations of placental disease are diverse and severe and include fetal death, distress, hypoxia, shock, anemia, polycythemia, infection, congenital anomalies, and neoplasia.

The implantation site is normally in the upper uterus but may be in the lower segment, in the tubes, or, rarely, in the abdominal cavity. Maternal anatomic factors may contribute to abnormal implantations. Abdominal and tubal (ectopic) pregnancies are potential disasters for both mother and fetus; except for a rare surviving abdominal fetus, fetal loss is nearly uniform, and maternal mortality and morbidity are common.

Placenta previa is associated with multiparity and places the fetus at risk in the event of hemorrhage; premature delivery, usually by cesarean section, is necessary. Abruption of the placenta often is associated with maternal problems, including preeclampsia, hypertension, renal disease, and multiparity. Sudden fetal death may occur after an extensive placental separation; lesser degrees of separation can result in hypoxia and acute fetal stress. Bleeding from placenta previa and abruption is usually maternal but can be fetal and sufficient to cause fetal hypovolemia and anemia.

Cord abnormalities are unusual but may have severe consequences. A short umbilical cord may be complicated by abruption. True knots are unusual, but they do occur and can cause fetal stress. Vasa previa and velamentous cord insertion are difficult to identify before labor but can result in fetal compromise or fetal exsanguination. A circumvallate placenta is associated with fetal growth restriction. Vascular abnormalities within the main placental structure occur rarely; fetal risk in monochorionic multiple pregnancies includes the possibility of twin-to-twin transfusion syndrome, in which arteriovenous vascular anastomoses result in blood flow between the fetuses and in severe circulatory problems for recipient, donor, or both.

A vascular abnormality of the cord observed in 1% of pregnancies is a 2-vessel cord with a single umbilical artery, rather than the normal 2. Current evidence suggests that anomalies may be associated with a 2-vessel cord. The risk for associated abnormalities, including fetal growth restriction, renal abnormalities, and aneuploidy, is approximately 7%.

Premature rupture of membranes (PROM) is a major contributor to perinatal mortality and morbidity. It is defined as rupture that occurs before the onset of labor and is usually spontaneous. Artificial rupture of membranes may be accidental during an examination or may be used to augment labor. Regardless of classification, the prenatal care team must be aware that an inevitable process of increased fetal risk begins soon after rupture and that prospective treatment protocols are desirable. Most protocols stipulate evaluation and treatment in relation to the time since rupture. Prolonged rupture of membranes, which most authorities consider to be 18 hours after rupture, is the beginning of increased risk.

The primary cause of fetal and maternal morbidity and mortality in prolonged rupture of membranes is sepsis. At term, labor occurs within 24 hours of rupture in 80% of pregnancies; in preterm pregnancies, labor begins within 24 hours in less than 50%. The cause of preterm PROM is often not clear, and except for entities such as an incompetent cervix or history of a preterm delivery, no statistical correlation has been found with prior risk factors.

The frequency and degree of inflammation of membranes, cord, or fetus vary directly with time and onset of labor. Infection apparently ascends to the fetus through the cervix, with labor accelerating the process. Antibiotics given before delivery are of uncertain value in providing effective maternal treatment, but they do prevent some cases of sepsis in the fetus and newborn. Such is particularly the case of chemoprophylaxis for

prevention of group B streptococcal (GBS) infection. Current practice recommendations include culture of all pregnant women for GBS infection between 35 and 37 weeks' estimated gestational age, with treatment at the time of labor with intravenous antibiotics for those found to be positive. Women with GBS urinary colonization or women who have previously had an infant with invasive GBS disease should receive intrapartum chemoprophylaxis; prenatal culture screening is not necessary.

A dilemma in fetal risk management occurs in the PROM pregnancy that is significantly preterm. The fetus in this situation is at risk not only from infection but also from premature birth and its complications, especially respiratory distress syndrome. The physician has available prepartum agents (corticosteroids) that seem to accelerate pulmonary maturity and improve postpartum status overall in certain populations. A 2000 National Institutes of Health Consensus Development Conference reiterates the previous recommendation for antenatal treatment with corticosteroids for fetuses between 24 and 32 weeks' gestation that have preterm PROM. A single rescue course of antenatal corticosteroids may be considered if the antecedent treatment was given more than 2 weeks prior, the gestational age is less than 32 $\frac{6}{7}$  weeks and the risk for delivery within a week is estimated to be high.

There may be an increased risk for neurologic sequelae among babies born prematurely after PROM. An increased incidence of periventricular leukomalacia and cerebral palsy seems to be at least associated with, if not caused by, intra-amniotic infection. Whether immediate induced vaginal delivery or cesarean section delivery with preterm PROM will decrease these risks is unknown at present.

### Maternal-Fetal Unit

Fetal risk and poor perinatal outcomes are often associated with pathophysiologic processes in which both mother and fetus play an integral role. Causality in some situations is well understood, as in, for example, alloimmunization, but causality for other situations such as preeclampsia is not yet clear. A major factor in the risk for adverse neonatal outcome relates to fetal age at the time of delivery. At present, in the United States and worldwide, the mean gestational age at delivery is 39 weeks. Infants delivered between 37 $\frac{7}{7}$  weeks and 38 $\frac{6}{7}$  weeks are at higher risk for neonatal morbidity and mortality than those born between 39 $\frac{0}{7}$  weeks and 41 $\frac{6}{7}$  weeks. Neonatal mortality and morbidity are higher after 42 $\frac{0}{7}$  weeks compared to 38 $\frac{7}{7}$  weeks through 41 $\frac{6}{7}$  weeks, and also higher at 37 $\frac{7}{7}$  weeks through 38 $\frac{6}{7}$  weeks than at 39 $\frac{0}{7}$  weeks through 41 $\frac{6}{7}$  weeks. Infant mortality is lowest for births at 39 $\frac{0}{7}$  weeks through 41 $\frac{6}{7}$  weeks.

### Premature Birth

Prematurity and its complications are the prime contributors to perinatal mortality and morbidity. The problems of prematurity and low birth weight are similar but not identical.

The prevention and management of premature birth has been and remains the primary objective of

perinatal care providers. Prematurity is multifactorial in origin, and its causes will likely remain unclear for the foreseeable future, inasmuch as the precise mechanisms that cause normal labor have yet to be elucidated. Many factors that contribute to fetal risk precipitate adverse outcomes directly or indirectly through premature birth.

### Pharmacologic Intervention

Tocolysis, or inhibition of uterine activity, is therapy directed at preventing premature birth once labor has begun. Pharmacologic agents have been used with this intent for years with minimal success.

The theoretical basis for the use of  $\beta$ -mimetic drugs as tocolytics is their inhibitory effect on uterine contractions through activation of  $\beta$ -adrenergic receptors.  $\beta$ -Adrenergic receptors are subdivided into  $\beta_1$  and  $\beta_2$  groups, with the latter dominant in blood vessels and the uterus. Isoxsuprine hydrochloride (a derivative of catecholamine), ritodrine hydrochloride, and terbutaline sulfate have been used and are thought to be effective in depressing uterine contractions. A  $\beta$ -mimetic that has a narrow effect on only the uterus has yet to emerge. Thus, maternal and fetal or neonatal side effects do occur, with cardiovascular, pulmonary, and metabolic complications documented. For example, neonatal hypoglycemia is a recognized complication of isoxsuprine therapy.

Calcium antagonists such as nifedipine are now used as an adjunct for tocolysis. Magnesium sulfate is no more effective than other agents but is commonly used because of a better maternal side-effect profile than the  $\beta$ -adrenergic agents, as well as its efficacy as a neuroprotective agent. Prostaglandin synthetase inhibitors may have a future role, but their use is limited because of their potential vasoactive effect on the fetus, especially on the ductus arteriosus.

Tocolytic therapy can be beneficial between 26 and 33 weeks' gestation. Then a relatively short delay of preterm delivery through tocolysis or other interventions is long enough (24–48 hours) to allow administration of corticosteroids for the enhancement of fetal lung maturity and maternal antibiotics for GBS sepsis prophylaxis.

### Prevention of Prematurity

Prevention of preterm birth is an area of ongoing research. Evaluation of lifestyle factors associated with preterm delivery and the subsequent modification of identified risk factors have yielded mixed results. More recent efforts have focused on cervical insufficiency and hormonal effects.

The use of weekly progesterone to decrease the risk for recurrent preterm birth in subsequent pregnancy seems promising because the biggest risk factor for preterm delivery is a history of previous preterm delivery.

Physicians can play a major role in such preventive programs because they ensure that the need for intervention is documented and that intervention occurs. In addition to management of specific medical problems, alterations in work and home environment may be necessary. Good prenatal care and early work leave may be very important. Countries in which such

policies exist, such as Sweden, have low prematurity rates, but whether this circumstance is an association or a contributing relationship is unknown at present.

### Multiple Gestation

The incidence of multiple gestation has recently and remarkably increased because of the application of newer reproductive technologies to treat infertility, although as reproductive technology is refined, the incidence of higher order multiple gestation is decreasing.

Spontaneously occurring multiple gestation is also relatively common (twins occur naturally in approximately 1 in 88 births). Regardless of the source of multiple gestation, fetal risk is increased. These risks range from those that are placental in origin, such as twin-to-twin transfusion, to rare fetal malformations, as in conjoined twins, to the much more frequent problems of prematurity and obstetric complications. Multiple gestation is among the 3 most common causes of prematurity. Complications of labor and delivery increase the risk for hypoxia or trauma, with the second-born twin being more susceptible to damage than the first.

### Obstetric Complications

Obstetric complications jeopardize the fetus, the most dire manifestation being intrapartum fetal death. Even the most healthy fetus is at increased risk during labor and delivery. Stress to the fetus may be documented retrospectively by low Apgar scores, poor recovery after birth, and subsequent complications. A fetus chronically compromised by adverse factors, such as diabetes in pregnancy, may be compromised further by obstetric problems.

Abnormal presentations, such as breech and transverse lie, greatly increase fetal risk, as does cephalopelvic disproportion (a mismatch between the maternal pelvis and the fetal head). Malproportion can be predominantly fetal, as in congenital hydrocephalus, or maternal when congenital pelvic bone abnormalities exist.

### Abnormal Growth and Gestation

Discrepancies between fetal growth and gestation are often manifestations of an underlying disease process but may occur without apparent cause. Regardless of cause, discrepancies in growth and gestation can often result in such severe risk to the fetus as to be more worrisome than the underlying problem. Postmaturity occurs much less often than prematurity, but it presents increased risk to the fetus. Continued growth in utero increases the risk for macrosomia and birth trauma. Placental insufficiency may result in the development of hypoxia and acidosis before or during labor that is characterized by non-reassuring fetal heart rate, poor Apgar scores, and perinatal hypoxic encephalopathy. Meconium passage is common and poses a risk for meconium aspiration syndrome; it may also signal peripartum infection.

Deviations of growth and gestation can be cumulative for fetal risk. The premature infant also affected by IUGR tolerates intrauterine stress poorly, may

exhibit respiratory distress syndrome or apnea after birth, and is at risk for the development of hypoglycemia. New information is emerging about the long-term effects of fetal growth restriction. Fetal nutritional adaptations to placental insufficiency may persist through adulthood because the risk for coronary artery disease and chronic hypertension is increased among adults who were born with IUGR. The physician should appreciate that evaluation of the fetus or newborn by birth weight and gestational age can provide specific information that facilitates diagnosis and treatment.

### Alloimmunization

Alloimmunization is a disease of the maternal-fetal unit that has decreased in incidence because of successful efforts to prevent Rh disease with Rh-globulin (RhoGAM). Passage into the maternal circulation of fetal red cells, which possess antigens not present in the mother, stimulates production of antibodies. Maternal antibodies of the immunoglobulin G (IgG) class cross the placenta, resulting in a hemolytic process in the fetus that can be severe. The initial alloimmunization can occur with blood transfusions, with spontaneous or induced abortion, or with the first or subsequent pregnancy. Small amounts of red cell antigen contained in blood measuring 1 mL or less (especially if repeated) can cause an antibody response even in normal pregnancies. Sensitization risk is increased by complications such as preeclampsia or cesarean delivery.

Rh incompatibility is associated with a variable but often severe sensitization that can cause stillbirth, massive fetal erythrocytosis or erythroblastosis, anemia, hydrops fetalis, and other systemic manifestations. Hyperbilirubinemia occurs in the newborn and to a lesser degree in utero, whereas the maternal liver clears bilirubin.

The incidence of fetal Rh disease varies with the prevalence of Rh negativity. This genetically determined state is not often documented in Asians and Native Americans; however, it occurs in 15% of whites, resulting in the possibility of approximately 9% of their pregnancies involving an Rh-negative woman carrying an Rh-positive fetus. Despite prophylaxis with RhoGAM for the D antigen, alloimmunization still occurs in response to several other red cell antigens for which there is no prophylaxis available, including c, C, e, E, Kell, Kidd, and Duffy. These *minor* antigens can cause very serious hemolysis. Some patients acquire more than 1 hemolytic antibody, typically after blood transfusion.

Since the delineation of the cause of Rh sensitization, a wide range of diagnostic and therapeutic methods have become available that make Rh incompatibility treatment a paradigm for intensive perinatal care. Today's routine procedures for the disease include initial screening for the presence of alloimmunization and for Rh-negative women who are still candidates for prevention with RhoGAM. If hemolytic antibody is detected, then maternal serum levels and amniotic fluid analysis can assess the possibility of severe fetal illness. Amniotic fluid can be analyzed by polymerase chain reaction (PCR) DNA analysis to

determine fetal blood type and the risk for hemolytic disease. Noninvasive methods of diagnosis of fetal anemia have been developed, which use ultrasound assessment of fetal cerebral blood flow in the middle cerebral artery. Peak systolic velocity in the middle cerebral artery increases as anemia worsens. This noninvasive option for monitoring decreases the risk accrued with serial amniocentesis, which can include infection, worsened sensitization, and loss of pregnancy. When a high hemolytic risk is detected, by either ultrasound or amniocentesis, fetal blood sampling by the percutaneous umbilical route can be performed so that an accurate assessment can be made and so that in utero blood transfusion may be administered. The timing of delivery includes consideration of fetal health, the possibility of in utero transfusion, and the degree of prematurity. Immediate, aggressive neonatal intensive care, including exchange transfusion and cardiopulmonary support, may be indicated.

Incompatibilities of the ABO system result from the presence of maternal anti-A or anti-B antibodies when the fetus's blood type is group A or B and the mother's is group O. Severe hemolysis is much less common, even though ABO incompatibility is potentially present in approximately 20% of pregnancies. Fetal erythrocytes seem to have fewer antigenic loci, and maternal antibody appears in IgA, IgM, and IgG forms, with only the latter crossing the placenta. These facts may explain why ABO alloimmunization is usually of greater concern in the newborn than in the fetus. Stillbirths and hydrops fetalis are rare, but prolonged neonatal hyperbilirubinemia occurs often.

### Gestational Hypertension

Hypertension of pregnancy is a major contributor to fetal risk. A group of diseases seen only in pregnancy and presenting with acute and chronic manifestations of hypertension, edema, and proteinuria may be lumped together in this category. *Preeclampsia* is another term for the basic process, which can be severe; when convulsions or coma occur, *eclampsia* is present. Chronic hypertensive vascular disease with pregnancy is thought by many to be a separate disease state that can have superimposed preeclamptic manifestations.

Premature birth is increased in incidence because early delivery is often elected on maternal or fetal indication. As the severity of the disease increases, and particularly when eclampsia develops, stillbirth and maternal death become much more frequent. IUGR is seen in a third of perinatal deaths associated with preeclampsia. For the fetus, this disease process presents a bleak perspective; fetal stress is significant, and labor and delivery are often premature and timed for maternal treatment rather than for fetal well-being. Neonatal complications are many and severe.

Successful perinatal management of preeclampsia relies heavily on early detection during prenatal care. When the process is discovered, intensive perinatal care may be necessary, with seizure prophylaxis with magnesium sulfate a mainstay of therapy. Severe preeclampsia is a significant maternal threat and may require a decision to deliver a premature baby. Proper expectant management requires careful maternal and fetal surveillance, including assessment of fetal well-being

by nonstress testing, biophysical profile, amniotic fluid volume determinations, Doppler studies of umbilical blood flow, and ultrasound studies of fetal growth.

### Intrauterine Infections

The medical community's understanding of the scope of the problem of intrauterine infections and their fetal effects has broadened considerably but is probably far from complete. Expression ranges from fetal loss caused by spontaneous abortion and stillbirth through severely debilitating congenital anomalies resulting from teratogenic effects, to subtle systemic manifestations, including those of the CNS, not detected until later in childhood when problems with higher cerebral function and behavior become apparent.

The important infectious agents include viruses, bacteria, spirochetes, and protozoa. The route for infection varies with the agent and can be transplacental, ascending through the cervix, with or without the rupture of membranes, which provide an imperfect protective cover, as well as through direct contact with the fetus during passage through the vagina.

The pediatric physician needs to have a basic appreciation for the variety of intrauterine infectious agents and the pathophysiologic processes and clinical problems they invoke. Table 80-1 is a modification of the TORCH acronym that has served well for several decades.

### Human Immunodeficiency Virus

Fetal, intrauterine, and peripartum considerations are but a small part of the story of HIV; a complete discussion appears in Chapter 268, Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome. Given the magnitude of the HIV/AIDS problem and that of the 3 predominant modes of transmission in the United States (sexual contact, percutaneous contact with contaminated sharps, and fetal or infant contact with an infected mother), 2 involve reproduction, the pediatrician must know the specifics of transmission and intervention. The newly developed ability to decrease vertical transmission from mother to fetus makes universal screening of pregnant women for HIV imperative. The fetus can be infected in utero, although the exact timing is uncertain; other possibilities for transmission include transplacental or peripartum, as well as postpartum (through breastfeeding). The timing of the expression of disease in children is variable and is thought to be determined by whether the infection was acquired before delivery or during parturition. Without antiviral therapy, approximately 25% of babies born to HIV-infected women will become infected themselves. The use of antepartum, intrapartum, and postpartum multiple-agent antiretroviral prophylaxis may decrease the risk for congenital infection to 2%. Even further decreases in transmission may be associated with cesarean delivery or vaginal delivery within 4 hours after rupture of membranes. Whether cesarean section delivery is protective for fetuses of women who have very low or undetectable viral loads is uncertain. Newborns discovered to be at risk should be continued on antiretroviral agents until their infective status becomes clarified. In the United States, where safe artificial milk is available, breastfeeding is contraindicated in HIV-infected women.

**Table 80-1**      **Maternal-Fetal Infections: TORCH**

INFECTION	ORGANISM	TRANSMISSION	COMMENTS
T Toxoplasmosis	<i>Toxoplasma gondii</i>	Transplacental	Most common congenital parasitic infection in US; domestic cat is primary host; risk of infection is highest in third trimester, but fetal effects are less severe; prenatal diagnosis by PCR or tissue culture
O Other	<i>Listeria monocytogenes</i>	Vertical or horizontal (environmental exposure)	Foodborne, gram-positive bacillus; isolated from livestock and fowl; outbreak related to consuming contaminated cheeses, raw vegetables, milk; infection during first and second trimester associated with high rates of fetal death Diagnosis: + body fluid cultures
	Syphilis ( <i>Treponema pallidum</i> )	Transplacental	Transmission at any stage of pregnancy; prevalence increasing in the US; risk factors: young age, inadequate prenatal care, substance use, multiple partners, history of STIs, inadequate treatment for prior infection; maternal screening (VDRL, RPR) at entry into prenatal care and at delivery is key
	Varicella-zoster	Transplacental	Varicella embryopathy caused by transmission during first 20 weeks of gestation; can cause limb deformities and cicatricial skin scarring
	Parvovirus B 19 (Fifth's disease)	Respiratory (most common), hematogenous (transplacental), vertical	Infection typically more common in spring and summer; transmission risk highest in first and second trimesters; can cause fetal hydrops and increased nuchal translucency in the first trimester Maternal testing for antiparvovirus B 19 IgM and IgG, amniotic fluid PCR
	Group B <i>Streptococcus</i> , <i>Gonococcus</i> , HIV, mumps, enteroviruses, tuberculosis		
R Rubella	Rubella virus	Transplacental	Rare in countries with universal rubella vaccination; fetal infection rates highest with exposure in the first trimester; diagnosis maternal infection by rubella-specific IgM
C Cytomegalovirus	Human Cytomegalovirus (CMV, herpes virus 5)	Congenital, transplacental; 50% infected at birth	Most common congenital infection; transmission more common in primary maternal infection, results in 30%–40% fetal infection; maternal disease typically mild; infection risk increases with young maternal age, single status, non-white race, and exposure to young children Universal prenatal screening is not routine; prenatal diagnosis: anti-HCMV IgM and low avidity anti-HCMV IgG
H Herpes Simplex	Herpes simplex virus (HSV) 1 and 2	Intrapartum Transplacental is rare	Neonatal infection usually from primary genital infection with HSV 2; mother is often asymptomatic; neonatal disease is typically severe Diagnosis: HSV-PCR + HSV cultures

### Rubella

Rubella virus is recognized as a potent teratogen. Infections during the first trimester result in approximately 20% of fetuses being severely damaged or malformed, with second-trimester involvement damaging 10%. Third-trimester infection has presented few clinical problems. The expression of rubella syndrome is variable. Manifestations of first-trimester fetal disease can be severe (eg, abortion, stillbirth, severe rubella syndrome). Severe rubella syndrome includes growth restriction, eye defects (cataracts and microphthalmia), congenital cardiac defects, deafness, thrombocytopenic purpura, hepatosplenomegaly, bone lesions, pneumonitis, and cerebral defects (microcephaly, encephalitis, intellectual disability, and spastic quadriplegia). Infections in the second trimester are variable and tend to be less severe.

The high fetal risk and potentially devastating consequences of intrauterine rubella have stimulated aggressive efforts to prevent maternal rubella. Congenital rubella is a reportable disease. Vaccination of children between the ages of 1 and 12 years is routine. Administration of vaccine to women of childbearing age has been controversial because of concern of possible vaccine effects on the developing fetus. However, a registry of cases in which women received vaccine within 3 months of conception has found no cases of congenital rubella syndrome. Vaccine virus was cultured from fetal and placental tissue, but teratogenic effects were not seen. Preconception counseling should include rubella serotesting to determine the need for vaccination before conception occurs.

### Cytomegalovirus Infections

The cytomegaloviruses (CMVs) may be the most common cause of congenital infections, occurring in somewhat less than 1% of births. This group of viruses is widespread and produces various apparent and inapparent infections in the general population: 58% of women of childbearing age are seropositive. Among uninfected women, 1% to 4% will develop a primary CMV infection during pregnancy, with approximately one-third of these women shedding virus to their fetus transplacentally. Fetal infection usually occurs through the placenta.

The fetal disease has been called *cytomegalic inclusion disease* because of the large inclusion-bearing cells found in urine and many organs. Severe cytomegalic inclusion disease includes hepatosplenomegaly, microcephaly, cerebral calcifications, mental and motor manifestations, and chorioretinitis. Reviews suggest that expression of intrauterine infections is variable and that full recognition of incidence is yet to come. Serologic tests for CMV are available and can provide presumptive evidence for infection; however, reliability is not as good as with rubella titers, and a vaccine is not available. CMV antibody testing of infants reflects the maternal antibody status. Consequently, congenital CMV infection cannot be diagnosed if the infant is tested more than 2 to 3 weeks after birth. Urine CMV culture is a good indicator of recent or active infection. Among infants born with congenital CMV infection, approximately 80% are asymptomatic. One in 750 CMV-infected infants will

develop permanent CMV-related sequelae. CMV is the most common cause of nonhereditary hearing loss in children.

### Herpes Simplex Virus Infections

Herpes simplex virus (HSV) infections in humans result from 2 strains, types 1 and 2, each with distinct serotypes yet some cross-reactivity. Perinatal disease is usually associated with type 2, although type 1 is more common in the general population. Type 2 HSV produces genital lesions and in most instances is transmitted sexually. Herpetic disease in the fetus or newborn is relatively rare but can be devastating. Transmission occurs by direct contact at birth or by ascending transcervical infection after rupture of the membranes. Transplacental infection early in pregnancy with fetal manifestations similar to those of CMV infection has been documented but is rare. Prophylaxis against recurrent HSV outbreak is suggested late in the third trimester through delivery.

Newborn manifestations of intrapartum contact are well known. They range from vesicular lesions of the skin to encephalitis and severe systemic disease, with a mortality of more than 90% without treatment and severe CNS morbidity in those who survive. Expression is probably linked to primary versus recurrent maternal disease, being more intense in the former.

A major recent development is the success of antiviral agents in the treatment of systemic herpes infection, in particular encephalitis. Early diagnosis and treatment are essential. Prevention is desirable and possible. (See the discussion of herpes infections in Chapter 267, Human Herpesvirus-6 and Human Herpesvirus-7 Infections.) Current suggested management for a pregnant mother who has active genital lesions is a cesarean delivery to prevent fetal inoculation by passage through the vagina.

### Toxoplasmosis

Toxoplasmosis is caused by an intracellular protozoan parasite, *Toxoplasma gondii*. Infection is widespread, is congenital or acquired, and varies in expression from almost asymptomatic to generalized and fatal. The fetus is at risk for death when the infection occurs early in pregnancy or may be born with fully developed disease indicative of a long intrauterine course. Chorioretinitis, cerebral calcification, hydrocephalus or microcephaly, hepatosplenomegaly, and a host of systemic manifestations are observed. Long-term sequelae, especially involving the CNS, are present in most of the infants who have severe infection and survive.

Pregnant women are thought to become infected through consumption of raw or undercooked meat or by ingestion of oocysts from soil or contaminated food. They may also become infected by exposure to cat feces. Prevention of toxoplasmosis in pregnancy is possible by careful handwashing after changing cat litter, gardening, or handling raw meat. The incidence of the perinatal disease is higher in certain locales.

Detection of *Toxoplasma* antibody by a reference laboratory can document the onset of infection if IgM antibody appears coupled with a rise of IgG antibody in paired samples over at least 2 weeks. Antibody levels

can remain high for years; unchanging elevated levels indicate old infection. Infection before pregnancy seems to prevent congenital disease; however, maternal coinfection with HIV may result in reactivated maternal parasitemia and congenital infection. If toxoplasmosis is suspected by serologic testing, then amniotic fluid or fetal blood can be tested by PCR for *Toxoplasma* DNA. Treatment with pyrimethamine and sulfadiazine is effective in decreasing the severity of congenital infection. Congenital toxoplasmosis may be inapparent at birth and not recognized until later in infancy or early childhood. (See Chapter 308, Parasitic Infections.)

### Other Intrauterine Infections

Fetal syphilis is caused by transplacental passage of *Treponema pallidum*. Fetal infection has been thought not to occur before the 18th week of gestation, but this assumption is disputed. Pregnancy in a woman who has primary- or secondary-stage disease may result in stillbirth. Other manifestations vary from presentation in the newborn to those appearing in the first 2 years of life or later. In general, the earlier the onset of infection, the more severe the lesions will be. Severe fetal infection manifests in early infancy by osteochondritis and periostitis, rhinitis (snuffles), rash, and mucosal fissures or patches. Premarital and prenatal screening for syphilis, in conjunction with antibiotic treatment, has effectively decreased the incidence of intrauterine disease, especially the more severe or classic manifestations. Unfortunately, a resurgence occurred in the late 1990s. Recently trained physicians have not had the experience in recognizing congenital syphilis that many of their older colleagues have had, which sometimes results in a delayed diagnosis. Detection of disease during pregnancy and treatment with penicillin will arrest development of the fetal disease. Penicillin remains the treatment of choice for syphilis during pregnancy, even if desensitization for penicillin allergy is required. (See Chapter 330, Sexually Transmitted Infections.)

*Listeria monocytogenes* is a gram-positive bacillus that probably plays an important role in overall fetal wastage. Incidence varies widely; infection is associated with ingestion of contaminated ready-to-eat food products. Fetal death may occur after a relatively mild systemic maternal disease. *Listeria* chorioamnionitis can be diagnosed by amniocentesis, and successful antibiotic treatment is possible. Neonatal manifestations include systemic disease at birth or a delayed appearance as meningitis in the second to fifth weeks of life, with a characteristic monocellular cerebrospinal fluid.

GBS disease has many similarities in presentation to that of *Listeria* and is a more common problem (see Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn). Infection is acquired by exposure to organisms during parturition. Maternal immune status and bacterial subtype are important determinants of virulence. The Centers for Disease Control and Prevention, the American College of Obstetrics and Gynecology, and the American Academy of Pediatrics recommend assessing colonization status at 36 weeks' gestation by culture and treating all

colonized women as labor commences. If GBS status is unknown at the onset of labor, then women who have risk factors such as prolonged rupture of membranes, preterm labor, fever or systemic manifestations, or a previous child who had GBS disease should be treated.

All neonatal services should have a structured approach to identifying and treating patients at risk for or having GBS disease in its 2 dominant modes of presentation: a fulminant hemorrhagic pneumonitis in the first hours after birth, or neonatal meningitis that appears a few days or weeks after birth.

Other known intrauterine infections include agents of all known classes; undoubtedly, many others are yet to be discovered. Many viruses can cause fetal infection, including varicella, coxsackievirus, mumps, rubeola, echovirus, and hepatitis. *Mycoplasma pneumoniae* also is an important perinatal agent, and malaria is a significant fetal threat in many areas of the world.

### FETAL ASSESSMENT

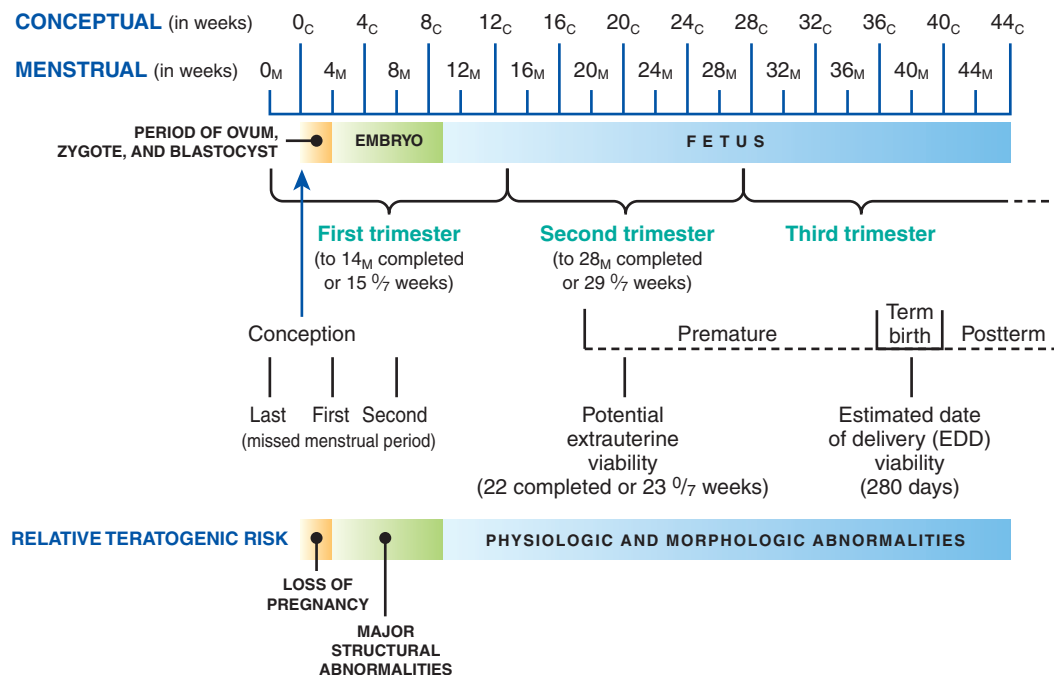

Physicians use menstrual dating when describing the course of human pregnancy, beginning with the first day of the last menstrual period. Others use conceptual dating and a time line that begins with conception or approximately 2 weeks after the last menstrual period. Occasional confusion arises when the differences between these 2 conventions are not appreciated. Furthermore, physicians discuss pregnancy in terms of portions of weeks, such as 36%, or the beginning of the 36th week. By use of menstrual dating, a pregnancy is thus in the 37th week (37%), when it is considered to be at term. This concept is similar to a child not being 1 year of age until the child's first birthday, on the 366th day of life.

The typical human pregnancy lasts 36 to 40 weeks from fertilization or 38 to 42 weeks from the last menstrual period (by menstrual dating). Fetal development begins at fertilization, when a sperm combines with an oocyte to form a zygote. The fetal life span is defined here in the broad sense to include the entire gestational interval (Figure 80-3). The human product of conception technically becomes a fetus at the end of the eighth week after fertilization and remains so until birth.

Development proceeds from conception to birth in 3 stages: the ovum, zygote, and blastocyst; the embryo; and the fetus. The *conceptus*, or product of conception, comprises all the structures that develop from the zygote, both embryonic (the embryo or fetus) and extraembryonic (the membranes and the placenta).

The stage of the ovum, zygote, and blastocyst, illustrated in Figure 80-1, begins with fertilization, wherein a single haploid sperm (23 chromosomes) enters the oocyte (haploid female ovum with 23 chromosomes). This stage usually takes place within the ampulla of the fallopian tube. The fertilization process is complicated and takes up to 24 hours before the genetic material from the 2 haploid cells fuses to form a diploid cell, the *zygote*, with a full complement of genetic material (called the *stage of syngamy*).

The *preembryo* consists of the developing cells, produced by division of the zygote, and lasts until

**Figure 80-3** Fetal life span by conceptual and menstrual dating. Note timing of important events and relative teratogenic risk.

the formation of the *primitive streak*, approximately 14 days after the beginning of fertilization. The pre-embryonic stage has been of special interest clinically and ethically because sustaining human preembryos in vitro is possible for up to 6 to 9 days after fertilization.

Preembryo development, during the interval before implantation in the uterine lining, includes a series of morphologic changes. Progression proceeds from blastomeres, or individual cells, to a tightly compacted group of cells called the *morula*. The blastocyst, a mass of cells with a fluid-filled inner cavity, appears approximately 4 days after syngamy. Early mitotic divisions lead to totipotent cells that are able to produce all the products of conception. During this time, twinning becomes possible; by approximately day 7, differentiation leads to cells becoming individualized. The multicellular blastocyst with a trophoblast and an inner cell mass initially attaches to the maternal endometrial lining at day 8 or 9, and over the next several days it becomes embedded, thereby completing the process of implantation.

By the time of the first missed menstrual period (see Figure 80-3) the primitive streak has been formed in the embryonic disk, embryogenesis is beginning, and a critical time has passed during which up to 50% or more of fertilizations do not complete pre-embryonic development and implantation successfully. Thus, this stage is a period when the product of conception is at very high risk.

The *embryonic* period encompasses approximately weeks 3 to 8 and is characterized by the differentiation of all major organs that will be present in the fetus, the newborn, and the adult. Near the beginning of this interval, the woman usually becomes aware of

cessation of menstruation, and laboratory tests can confirm pregnancy.

During the pre-embryonic period, adverse conditions may cause the death of the products of conception. This event often occurs around the time when a menstrual period would have been expected, and fertilization may not be recognized. Adverse influences during the embryonic period can cause severe interruptions in the pattern of system development, resulting in major congenital anomalies in a surviving fetus. The embryo is recognizable as humanoid toward the end of this period; malformations such as neural tube defects resulting, for example, from maternal ingestion of carbamazepine, may be identified.

The *fetal* stage, the longest of the 3 stages of the fetal life span, ends with delivery. Growth in size is the most apparent change during this interval, but maturation of organ systems and bodily processes is equally important. The high incidence and problems of premature birth make the degree of organ and enzyme system maturation of compelling interest to the pediatrician. The development of pulmonary surfactant is probably the single most important maturational process directly affecting survival in premature infants.

The late fetal stage has become the focus of increasingly sophisticated diagnostic techniques. Ultrasonography not only provides images of the fetus but also facilitates invasive procedures, such as amniocentesis to obtain amniotic fluid, and fetal blood sampling. Magnetic resonance imaging can be used in selected cases to provide further diagnostic information. The pediatrician needs to keep pace with developments in this period because intrauterine treatment of the fetus seems destined to expand someday to include the addition or modification of genetic material.

### Intrauterine Growth and Nutrition

The pediatrician must have a firm conceptual framework of intrauterine growth to effectively evaluate and treat the healthy newborn and the atypical newborn. In particular, the common clinical problem of prematurity can be managed more appropriately if growth patterns as they relate to gestational age are appreciated.

The growth rate of the fetus is especially rapid from 12 to 16 weeks of gestation and again during its final months. Both of these rapid-growth phases are associated with events of immediate concern to the physician. By the end of the 16th week after fertilization, the size and activity of the fetus have reached the point that many multiparous and some primiparous women are able to feel fetal motion (*quickening*). This event can be a valuable marker when assessing fetal age and well-being. The late-growth phase can be monitored by several means, especially physical examination, including the measurement of the height of the fundus above the maternal symphysis pubis and ultrasound measurements.

The period from 8 to 12 weeks after fertilization begins with a fetus whose head makes up almost one-half of the total length. By 12 weeks the total length has doubled, but the head represents a smaller proportion. The 12- to 16-week interval is characterized by extremely rapid growth in length. In the 17- to 20-week interval growth slows somewhat, but extremities assume their relative proportions. The 21- to 25-week interval after fertilization is characterized by significant gains in both length and weight.

Twenty-one weeks after fertilization, or 23 weeks from the last menstrual period, represents an extremely important milestone because the threshold for extrauterine viability is currently recognized as occurring at approximately 22 to 25 weeks (menstrual dating), with neonatal intensive care necessary to sustain that potential. An important point to note is that at the threshold of viability, cognitive and neurologic impairment is common when the child has reached school age, and the level of impairment is greater than previously recognized with the use of standardized norms.

Many studies have attempted to quantify fetal growth through the use of postnatal data. Such growth curves, derived from measuring infants born at varying gestational ages, can give an approximation of intrauterine growth, but they have shortcomings. The baseline population is, by definition, atypical because the babies were born before term. In addition, the population of premature live births is very difficult to standardize for factors such as race, parity, socioeconomic status, maternal smoking, and maternal disease states.

Despite all this circumstance, intrauterine growth curves derived from postnatal data can be of great clinical assistance. The Colorado Intrauterine Growth Charts (Figure 80-4) are among the better known. They provide percentiles of intrauterine growth for weight, length, and head circumference. In addition, a weight-to-length ratio is shown. From weight and length data, a ponderal index can be derived to depict proportionality. The growth curves in Figure 80-4 were derived from a population of hospital-born and

non-hospital-born infants who had mixed racial backgrounds and were living at an altitude of approximately 5,000 feet. Intrauterine growth curves derived from live births in other populations show significantly different values, particularly at some of the higher percentiles. However, the basic sigmoid shape of the curve persists. A few investigators have questioned the sigmoid shape of the growth curve as artifactual because it is based on the inaccuracies of menstrual dating. They suggest that when ultrasound dating is used, the curves become linear. With the use of growth curves and ultrasound, fewer pregnancies now are delivered at 43 and 44 weeks' gestation.

Intrauterine growth curves for the last trimester of pregnancy can be very helpful in both fetal and neonatal medicine. That intrauterine growth is a steady process cannot be assumed without reservation; growth might occur in bursts of undetermined length. Monitoring individual fetuses for growth against the baseline of an intrauterine growth scale can be helpful.

Fetal nutrition can be conceptualized in basic parameters that are familiar to the pediatrician. As with the child, 2 basic processes are underway: accretion of substance for growth of new tissues, and oxidation or energy production for metabolism. Growth and development occur as a continuum from fetal to extrauterine existence, but the physiologic mechanism of nutrition for that continuum changes abruptly at birth when the principal fetal organ for respiration and nutrition (the placenta) gives way to other organs and systems.

Glucose is a primary nutrient for the fetus, with its transplacental passage providing material for energy and for contributions to the fetal carbon pool. Initially, tissue growth is the main location for carbon and other constituents, with the 20-week fetus having little or no fat and approximately 90% water in its body composition. By term, fetal body water has decreased to approximately 76%, a figure high by adult standards; fat, a material of high carbon content, constitutes approximately 16% of the fetus. These observations, coupled with the instability of neonatal glucose metabolism, when the baby is stressed by infection or other problems, should reinforce the importance of glucose metabolism in the perinatal period and particular respect for the relatively depleted stores of energy in the small premature or growth-restricted infant.

Amino acids, both essential and nonessential, are important as the building blocks of fetal protein synthesis. The uptake of essential amino acids through the placenta seemingly serves as a basic requirement for growth. Maternal nutritional state and placental function are crucial to fetal well-being and growth, whereas in the neonate, amino acids and nitrogen originate with digestion of milk and uptake through the portal venous route.

The physician dealing with the newborn must consider the prior fetal nutritional state. Fortunately, when the digestive system of the neonate is unable to function at a level sufficient to provide energy and growth, physicians have the knowledge and technology available to approximate the fetal nutritional state. Total parenteral nutrition effectively returns the baby to the

**Figure 80-4** Colorado intrauterine growth charts. These charts were developed from measurements of babies after birth. They remain useful as a means for determining relative growth status of a baby compared with a reference population. (Adapted from Lubchenco LO, Hansman C, Boyd E. Intrauterine growth in length and head circumference as estimated from live births at gestational ages from 26 to 42 weeks. *Pediatrics*. 1966;37:403–408.)

fetal state, in which all necessary nutrients, including essential and trace substances, enter directly into the circulation. Although this state can be maintained for reasonable intervals, such therapy does have complications, including infection and liver disease, making very long-term parenteral nutrition of the child much more problematic than it is for the fetus.

### Identification and Management of Fetal and Maternal Risk

Any factor that increases the possibility of adverse pregnancy outcomes contributes to risk. Medical risk includes physiologic, nutritional, obstetric, and genetic factors. Psychosocial risk includes psychological, social, environmental, and behavioral factors and personal habits. These 2 broad categories of risk often act

concurrently, and individual risks may overlap, accompany, or follow each other. The relationship between risk factors and adverse outcomes may be obvious, as with a specific toxic agent such as mercury; more often, however, risk is both subtle and cumulative.

### Preconception Care

Health before pregnancy has become increasingly recognized as an important determinant of pregnancy outcome. Preparation for pregnancy should begin before conception for both women and men, including assessment of risk and preventive or therapeutic intervention, including change of behavior. Box 80-1 illustrates the general categories and some specific problems that should be addressed in preconception care.

**BOX 80-1 Preconception Care Inventory****MEDICAL HISTORY**

- Reproductive
- Family
- Genetic
- Current medications
- Substance use, including alcohol, tobacco, and illicit drugs
- Abuse, physical and emotional
- Environmental exposures
- General physical examination
- Immunization when indicated (rubella, hepatitis B, varicella)

**SCREENING**

- Sexually transmissible infections, depending on risk assessment
- Genetic disorders based on racial and ethnic background and family history (sickle hemoglobinopathies,  $\beta$ -thalassemia,  $\alpha$ -thalassemia, Tay-Sachs disease, cystic fibrosis, fragile X syndrome, Duchenne muscular dystrophy)

**COUNSELING**

- HIV prevention and testing
- Abstinence from tobacco and alcohol
- Folic acid supplementation when attempting pregnancy and during first trimester
- Good control of preexisting medical conditions such as diabetes and hypertension

Modified from American Academy of Pediatrics. *Guidelines for Perinatal Care*. 7th ed. Elk Grove Village, IL: American Academy of Pediatrics and American College of Obstetricians and Gynecologists; 2012.

The concept of care before conception is related to, but not the same as, family planning; much more is involved than merely spacing of pregnancies. Wider acceptance of this concept within society may have a major effect on the outcome of pregnancy in such specific populations as adolescents. The role of the pediatrician in preconception and interconception care is vital.

The importance of preconception care was emphasized in 2006 by the Centers for Disease Control and Prevention, which convened a summit to discuss preconception care programs, research, and policy. The recommendations are specific to the implementation of health behavior, access to health care, consumer demand, research and surveillance for monitoring, and improving the health of women, children, and families. Box 80-2 summarizes the primary objectives of the panel recommendations of the Centers for Disease Control and Prevention.

**Prenatal Care**

A report entitled *Caring for Our Future: The Content of Prenatal Care*, published by the US Department of Health and Human Services in 1989, defines the 3 basic

**BOX 80-2 Recommendations to Improve Preconception Health and Health Care**

1. Improve the knowledge, attitudes, and behaviors of men and women related to preconception health.
2. Ensure that all women of childbearing age in the United States receive preconception care services that will enable them to enter pregnancy in optimal health.
3. Reduce risks indicated by a previous adverse pregnancy outcome through interventions during the interconception period, which can prevent or minimize health problems for a mother and her future children.
4. Reduce the disparities in adverse pregnancy outcomes.

From Centers for Disease Control and Prevention. Recommendations to improve preconception health and health care—United States: a report of the CDC/ATSDR Preconception Care Work Group and the Select Panel on Preconception Care. *MMWR Recomm Rep*. 2006;55(RR06):1–23.

components of prenatal care as early and continuing risk assessment, health promotion, and medical and psychosocial interventions and follow-up.

Previous discussion has emphasized that during the prenatal period, the fetus is undergoing rapid and continuous growth and development. Anything that jeopardizes this process must be recognized as a fetal risk factor and assessed. Major contributors to fetal risk are listed in Box 80-3.

Little doubt exists that prenatal care is associated with healthier babies and mothers. Much of the original interest in and emphasis on prenatal care involved pregnancy-induced hypertension and the use of periodic blood pressure determinations. Standardized schedules (with details such as number and timing of visits, procedures, and studies) are available. In addition, the US Department of Health and Human Services offers suggestions, including the addition of preconception care to traditional prenatal care. The tests available for fetal assessment are provided in Box 80-4.

**Assessing Fetal Status Before Labor**

The physician is obligated to make every effort to identify risk and practice expectant fetal medicine. Pediatricians must be familiar with the basic principles of techniques used to gather information. Family and reproductive history, fetal structure and growth, heart rate, and amniotic fluid and fetal blood analyses provide the basis for most of these methods. Some of these measurements are noninvasive, have been part of obstetric practice for years, and provide statistically valid information—for example, taking a history and measuring the size of the uterus. They are used to assess the need for other investigative techniques.

**Fetal Activity**

The duration, amplitude, and frequency of fetal movement after quickening and in the third trimester can provide important information about fetal well-being.

**BOX 80-3 Major Contributors to Fetal Risk****GENETIC**

- Chromosome abnormalities
- Inherited traits

**MATERNAL-FAMILIAL ENVIRONMENT AND LIFESTYLE**

- Socioeconomic status
- Social environment
- Physical environment
- Radiation
- Teratogens
- Nutrition
- Smoking or secondary exposure to smoke
- Drug or alcohol abuse
- Lack of prenatal care

**MATERNAL REPRODUCTIVE CAPABILITY AND HEALTH**

- Age, weight, height
- Reproductive tract abnormalities
- Maternal medical disorders
- Cardiac
- Respiratory
- Renal
- Hematologic disorders (eg, sickle cell disease, thrombocytopenia)
- Metabolic disorders (eg, diabetes, thyroid disorders, phenylketonuria)
- Epilepsy
- Emotional status/mental health

**PLACENTA AND MEMBRANE DISORDERS**

- Implantation (abdominal, tubal, previa)
- Vessel and cord complications
- Abruptio
- Premature rupture of membranes and infection

**MATERNAL-FETAL UNIT**

- Multiple gestation
- Obstetric complications
- Malposition and malpresentation
- Cephalopelvic disproportion
- Abnormal fetal growth and gestation
- Alloimmunization (erythroblastosis fetalis)
- Intrauterine infections
- Pregnancy-induced hypertension

An inactive fetus may be chronically compromised, and the rapid onset of inactivity in a previously active fetus can be ominous. Daily assessment of fetal movement has some value as a test of fetal well-being. Obstetricians often ask women to report if they perceive fewer than 10 fetal movements in a 2-hour period of close observation (*kick counts*). Change in fetal activity does not predict specific fetal abnormalities but warrants follow-up with more standardized tests of fetal well-being.

**BOX 80-4 Fetal Assessment****ANEUPLOIDY SCREENING**

- First-trimester screening
- Second-trimester screening
- Quadruple marker screening
- Genetic sonogram
  - Integrated screening
  - Sequential screening
  - Noninvasive prenatal testing/cell-free fetal DNA

**DIAGNOSTIC PROCEDURES**

- Chorionic villus sampling
- Amniocentesis
- Percutaneous umbilical blood sampling

**FETAL WELL-BEING ASSESSMENT**

- Fetal kick counts
- Nonstress test
- Biophysical profile
- Modified biophysical profile: nonstress test plus amniotic fluid index
- Contraction stress test
- Umbilical artery Doppler velocimetry
- Venous Doppler velocimetry
- Middle cerebral artery Doppler velocimetry

Fetal assessment modalities available at most regional centers. See text for more information.

**Fetal Heart Rate**

The normal fetal heart rate (FHR) settles in the range of 110 to 160 beats/min by the final trimester and is easily monitored by a Doppler device (after 10 weeks), a fetoscope (after 20 weeks), and a stethoscope (after 28 weeks). During labor, continuous electronic fetal monitoring is used widely but has not been conclusively shown to be better than intermittent auscultation, despite many large studies.

FHR decelerations, especially fewer than 100 beats per minute, are of concern because of an association with acute or chronic insult. Explanation for their presence must be sought. The list of possible causes is long and includes many that have a poor outcome, such as placental insufficiency. An intrinsic fetal cause, heart block, is not as ominous. Tachycardia usually occurs as an autonomic response to stimulation and can indicate fetal normality; it also may be associated with a maternal condition, such as pyrexia. Intrinsic fetal arrhythmias, such as supraventricular tachycardia, can result in secondary manifestations, including fetal hydrops.

**Nonstress and Contraction Stress Tests**

Tests that record FHR and the presence, absence, or temporal sequence of uterine contractions are used extensively. The FHR is driven by neurogenic reflex mechanisms similar to those seen in newborns.

The nonstress test (NST) observes FHR patterns by continuous fetal monitoring before the onset of

contractions. The interrelationship between FHR and fetal movement or spontaneous uterine contractions is observed. Such testing can begin at 26 to 28 weeks but is usually performed closer to term. NST is indicated for patients at risk for uteroplacental insufficiency and fetal death. It is repeated once or twice weekly. A normal or *reactive*, or category 1, NST is defined by a normal baseline heart rate (110–160 beats per minute), moderate variability (5–20 beats per minute), 2 or more accelerations of at least 15 seconds' duration, and a 15-beats per minute peak above baseline in a 20-minute period. A nonreactive or abnormal NST is defined as one that does not meet these standardized criteria and may actually show decelerations. The test has a false-positive rate for prediction of adverse fetal outcome of approximately 80%.

The contraction stress test (CST), or oxytocin challenge test, uses oxytocin-stimulated uterine contractions and records the FHR response. The NST is used more commonly; the CST is used by some physicians only after a nonreactive (abnormal) NST result. The presence of repeated late decelerations is considered problematic. Interpretations can be difficult, and relative and absolute contraindications exist for performing CST, in addition to a false-positive rate of approximately 50%. Interpretation requires experience.

### **Fetal Biophysical Profile**

Fetal well-being can be assessed through the use of multiple parameters identified on ultrasound. Items such as muscle tone, body movement, breathing movement, amniotic fluid volume, and results of the NST can be identified and a score derived in a fashion similar to that for determining an Apgar score.

The biophysical profile has been observed to have a reasonable correlation with fetal blood gas scores. Some investigators have found the combination of amniotic fluid volume assessment and NST to have equivalent performance to that of a biophysical profile.

### **Uterine Size**

The uterus and the products of conception are monitored closely at each prenatal visit. Measurements of fundal height above the symphysis are obtained and plotted; the umbilicus is reached by 20 to 22 weeks. Deviations from the expected curve may indicate a significant number of abnormal and high-risk states.

Fundal height at a level greater than expected may be the result of a miscalculation of dates, with the pregnancy being further along than anticipated. Another relatively straightforward cause of unexpectedly large uterine size is multiple pregnancy. Conversely, fetal causes of smaller than expected uterine size include pregnancy less advanced than anticipated and many problems that lead to IUGR.

The amniotic fluid volume deviations, oligohydramnios or hydramnios, may initially be detected by abnormal uterine size or fundal height. Confirmation and further study by ultrasonography should follow because ultrasound imaging can more precisely estimate the volume of fluid present and assess fetal structures.

The pediatrician also needs to be alert to particular fetal situations in preterm pregnancies in which oligohydramnios occurs, inasmuch as this may be associated

with a large number of disease processes, including IUGR and renal abnormalities with severely compromised urinary excretion. Under normal circumstances, amniotic fluid volume increases until 36 weeks and then decreases. Oligohydramnios thus can be associated with both postterm and postmature pregnancies. Renal agenesis (Potter syndrome) or dysplasia and structural and functional renal problems may not become evident until after birth.

Hydramnios may result from maternal problems, such as diabetes, or from fetal causes, such as tracheoesophageal fistula or diaphragmatic hernia. The pediatrician should immediately suspect fetal and neonatal abnormalities of the upper gastrointestinal tract because the normal circulation of amniotic fluid is interrupted on the absorptive side of the loop in these conditions. The baby will require special attention at birth and may require surgical intervention. CNS and neuromuscular abnormalities, such as myotonic dystrophy, impair fetal swallowing and cause hydramnios.

### **Ultrasonography**

Clinical ultrasound has had a profound effect on all aspects of perinatal medicine. A transducer, acoustically linked to the skin surface by a gel, transmits ultrasonic vibrations, and the returning sound echoes are processed electronically to produce a two-dimensional image. New technology is now allowing production of three-dimensional images, but two-dimensional imaging remains the standard of care of diagnostic ultrasound imaging in obstetrics. Three-dimensional imaging may be seen as an adjunct technology.

Two-dimensional images are used to evaluate fetal size and morphology. Doppler ultrasound is used to measure velocity of blood flow in fetal and maternal blood vessels. Color Doppler depicts local flow by color-encoding an estimate of the mean Doppler frequency shift at a particular position, thereby demonstrating direction and velocity of blood flow. This tool is useful in evaluating fetal heart structure on echocardiogram and may be used as an adjunct in antenatal monitoring in the setting of IUGR or maternal alloimmunization. Power Doppler ultrasound is a technique that encodes the amount of blood flow in color. Its usefulness includes evaluation of fetal vasculature and placental abnormalities.

Although no clinically untoward effects of clinical ultrasound have been documented in humans, potential structural and functional biologic effects have been hypothesized. Doppler ultrasound theoretically has greater potential for harm because of the continuous, rather than pulsed, wave and the amount of time in use. The US Food and Drug Administration, together with the American Institute of Ultrasound in Medicine and other organizations, has developed standards for safe information display.

Controversy continues about the usefulness of and indications for routine prenatal ultrasound examination; several large clinical studies provide conflicting results. An American College of Obstetrics and Gynecology *Practice Pattern Review* developed the following conclusions: specificity of ultrasound fetal anomaly survey is high (99%), sensitivity varies widely and depends on clinical setting and professional skill,

ultrasound is safe when used appropriately, specific indications should serve as the basis for the use of ultrasound in pregnancy, and the optimal time for a single ultrasound during pregnancy is between 16 and 20 weeks' gestation. The use of casual ultrasound without a medical indication should be avoided, and patients must be counseled about the limits of ultrasonography for prenatal diagnosis.

A National Institutes of Health consensus development conference in 1984 concluded that when an accepted medical indication exists, ultrasound improves pregnancy outcome, and the consensus committee listed many specific risk situations. Routine screening, identification of fetal sex, and parents' desire to see their fetus were not considered appropriate because of possible risk and ethical concerns. Estimates indicate that approximately 67% of pregnancies undergo ultrasound examination.

Ultrasound evaluations are an important part of evaluation of fetal well-being. Measurements of fetal growth pattern and distribution and amniotic fluid volume are important observations. A fetus for which biometric parameters are concordant and within acceptable range for gestational age and for which amniotic fluid volume is normal has a low risk for adverse outcome, such as stillbirth. Although the sensitivity varies with the type of birth defect and the skill of the operator, ultrasound can detect many birth defects. Ultrasound also is being used as a noninvasive tool to detect minor markers of aneuploidy.

### Fetal Surgery

Fetal surgery is a controversial intervention that has attracted considerable medical and public interest. Pediatricians should be aware of the general level of activity in this field because they may be consulted by families in their practices. The media and increasingly the Internet serve as informants about possible interventions, often without adequate attention to status of investigation and outcomes.

Fetal risk identification through accurate and timely prenatal diagnosis by ultrasound in conjunction with fetal sampling techniques and technical ability to intervene surgically through endoscopic or open techniques has resulted in attempts to correct fetal lesions that interfere with normal development. Fetal problems potentially amenable to surgical correction with resultant continued development in utero include urinary obstruction (urethral valves), twin-to-twin transfusion syndrome resulting from placental vascular abnormalities, and myelomeningocele. Neural tube defects have been subject to randomized controlled studies of intervention and outcome evaluation. Risks and benefit evaluation of fetal surgery should include the mother as well as the fetus. For further information, see Chapter 83, Fetal Interventions.

### Risk Assessment and Diagnostic Testing

An increasingly valuable technique of perinatal risk assessment involves maternal serum screening for markers that correlate with risk for specific outcomes. All pregnant women in the United States should be offered testing for detection of neural tube defects and

trisomy 18 and 21. Second-trimester (15–21 weeks) risk assessment includes analysis of  $\alpha$ -fetoprotein, unconjugated estriol, inhibin A, and human chorionic gonadotrophin—the quadruple, or *quad*, screen. The sensitivity of detection of spina bifida is approximately 80%, with a 3% to 5% false-positive rate. Ultrasound sensitivity for open neural tube defect is up to 95%. Women who have unexplained elevated serum  $\alpha$ -fetoprotein are at risk for adverse pregnancy outcomes other than neural tube defects, including IUGR and stillbirth. The sensitivity of a quad marker study panel for trisomy 21 is 79%, with a false-positive rate of 5%. First-trimester screening using 2 serum analytes,  $\beta$ -human chorionic gonadotrophin and pregnancy-associated plasma protein A, as well ultrasound measurement of the fetal nuchal translucency, allows risk assessment at 11 to 13 + 6 weeks' gestation, with a similar detection rate and false-positive rate. Noninvasive prenatal testing, or directed analysis of isolated cell-free fetal DNA from maternal serum, is also becoming available. This technique measures the relative proportions of chromosomes, giving a detection rate for trisomy 21 of nearly 99%. Ultrasound in the second trimester can be used to modify the risk assessed on either a quad screen or a first-trimester screen; the screen is based on the presence or absence of markers—subtle changes in fetal anatomy that are more likely to be associated with aneuploidy, such as hypoplastic nasal bone or thickening of the nuchal fold. Women whose screening results are positive are offered diagnostic testing, such as amniocentesis, and they often accept the procedural risk to achieve a definitive diagnosis.

### Amniocentesis

Amniotic fluid bathes and is swallowed by the fetus, and it contains fetal cells, urine, and other substances, including pulmonary surfactant. The technique for obtaining a specimen of this fluid by percutaneous aspiration has been made more successful by the use of ultrasonography.

Diagnostic amniocentesis at 15 to 18 weeks' gestation, in conjunction with ultrasonography, confirms placental localization, fetal size, and gestational age, in addition to providing information obtained from fluid analysis. Evaluation of fetal cells through karyotyping can detect chromosomal abnormalities before potential extrauterine viability so that termination can be considered. Fluorescent in situ hybridization studies are available that produce results for some aneuploidies within 48 hours, as opposed to the 10- to 14-day requirement for standard metaphase karyotype analysis. Molecular genetic studies on DNA extracted from fetal cells are expanding so rapidly that the pediatrician is advised to contact a prenatal diagnostic center to determine whether prenatal testing has become available for a specific disorder.

### Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves ultrasound-directed aspiration of trophoblastic tissue surrounding the gestational sac during the first trimester. The approach can be transcervical or abdominal. CVS is usually performed at 10 to 12 completed gestational

weeks, thereby providing information earlier than amniocentesis.

Studies of the safety and efficacy of CVS have found a higher rate of pregnancy loss and procedure failure than midtrimester amniocentesis. Some centers have higher rates of loss with transcervical than with transabdominal CVS. That CVS requires more professional experience than does amniocentesis is generally accepted. The advantage of CVS is more rapid and earlier diagnostic information, which allows more time for consultation and intervention, including abortion. The disadvantages of CVS include the slightly higher loss rate, lack of information about neural tube defect, and the possible need for later amniocentesis to clarify CVS results or to diagnose neural tube defect. Controversy has existed concerning possible limb reduction defects associated with CVS. The procedure is usually not performed before 10 weeks in an effort to minimize this risk.

### **Percutaneous Umbilical Blood Sampling (Cordocentesis)**

Direct aspiration of fetal blood by means of a needle placed transabdominally through maternal skin and into a fetal blood vessel, or percutaneous umbilical blood sampling (PUBS), is another technique facilitated by ultrasound that has improved fetal diagnosis and therapy significantly. Sampling is possible from approximately 17 weeks to term.

Common diagnostic indications for PUBS are the need for rapid fetal karyotype and evaluation of fetal alloimmune hemolytic disease. The main treatment is transfusion for fetal anemia. The PUBS technique is useful because it provides immediate fetal blood specimens for study of hemoglobin, platelets, blood gases, blood typing, and other parameters in the same fashion as studies in the neonate. Risk is a concern, with fetal loss a possibility. This technique requires sophisticated technology and expertise.

### **Fetal System Formation and Malformation**

Pediatricians and other health care providers must be prepared to discuss normal fetal development, as well as fetal malformation, with parents; this discussion increasingly includes management during pregnancy and the peripartum period. *Teratology* is the study of the causes, development, structure, and classification of fetal abnormalities. Modern prenatal diagnosis provides information about the presence of structural abnormalities in a large portion of cases well before birth.

Most major malformations and disruptions of system function can be categorized as being caused by genetic or intrauterine factors, maternal conditions, and drugs or other agents. Genetic factors have their origin in parental cell lines or in aberrations of initial cellular division after fertilization and are discussed in Chapter 96, Common Congenital Anomalies. Evaluation of risk for genetic disease has advanced rapidly as the techniques for prenatal diagnosis (including fetal cell and tissue sampling) have become increasingly sophisticated. Intrauterine factors include problems such as uterine abnormalities, amniotic bands, and umbilical cord or placental abnormalities. Mechanical

pressure from uterine constraint (as in severe oligohydramnios) causes morphologic changes categorized as a deformation sequence. If otherwise normally developing tissue is disrupted, as with the damage caused by amniotic bands from early amnion rupture, then the resulting damage is categorized as a *disruption sequence*. Maternal medical conditions that produce metabolic imbalance, such as diabetes mellitus and phenylketonuria, are teratogenic. The effect of maternal nutrition is of major concern, especially because the relationship between folic acid deficiency and neural tube defects now is well recognized. Drugs and other agents are a major concern because of the recognition that practically any drug is potentially teratogenic and because of the observation that chemical, radiation, or infectious agents may vary in degree of expression, depending on genetic predisposition or gestational age at the time of insult.

The major systems are discussed in the following sections, with attention drawn to the gestational time of origin of the major types of abnormalities.

### **Central Nervous System**

The CNS starts from an ectodermal origin at about day 18 of gestation; development continues through delivery and long after birth. It is susceptible to teratogenic agents throughout the embryonic and fetal periods and is most susceptible during the first half to two-thirds of the embryonic period.

The original neural plate develops into a neural tube that has cranial and caudal ends. The neural tube walls develop to become the brain and spinal cord; the inner part evolves into the ventricles of the brain and the central canal of the spinal cord. Brain development is complex and passes through stages of a forebrain, midbrain, and hindbrain, with subsequent development of the cerebrum, midbrain structures, pons, and cerebellum. Cells that were originally separated from the neural plate and became the neural crest develop into cranial, spinal, and autonomic ganglia, as well as the autonomic nervous system and chromaffin tissue, especially the adrenal medulla.

Malformations of the CNS confront the physician prenatally and postnatally through imaging studies, which may prompt pediatric and neurosurgery consultation. Some of these defects are among the most profound, such as the anencephalic baby or infants who have very large encephaloceles. Application of life-supportive technology, in the form of assisted ventilation and nutrition, to babies who have such problems has been the subject of much public debate, as has the issue of organ donation. Other anomalies, such as microcephaly, may be compatible with life for variable lengths of time but carry extremely bleak prognoses. Congenital malformations of the spinal column, especially those that have defects in overlying tissue, also pose major moral and ethical dilemmas to parents and health professionals, when potentially treatable complications are superimposed on a fundamentally poor prognosis. Some CNS lesions are of known origin, but others, such as meningomyelocele, may be the result of interactions between genetic predisposition and extrinsic factors. Preconception supplementation with folic acid will decrease the risk for neural tube defect.

Of major concern is the evidence that intrauterine exposure of the developing nervous system to substances such as cocaine or alcohol results in permanent functional morbidity, as well as structural changes. Although morphologic and behavioral changes often appear together, thus inviting the postulation of cause and effect, no reason exists to think that they are always related. Pediatricians should be familiar with resources available for management of neonatal abstinence syndrome.

The developing fetal brain is now known to acquire lesions that are clinically important to the infant and child. Spontaneous hemorrhagic lesions have been seen in the presence of alloimmune thrombocytopenia and cocaine exposure. Evidence is increasing of a link among intrauterine infection, preterm PROM, an increased risk for periventricular leukomalacia, and subsequent cerebral palsy.

### **Cardiovascular System**

The cardiovascular system is the first to function, with a rudimentary blood circulation beginning in the third week. Initially, 2 tubes fuse to form a single tube that evolves into the four-chambered heart and great vessels. By the end of the fourth or fifth week, partitioning of the chambers is complete, with 2 atria and 2 ventricles. Equally complex is the initial formation of a truncus arteriosus, aortic sac, and aortic arches, which evolve by the eighth week into a fetal circulatory pattern. This system undergoes changes in flow patterns during adjustment to extrauterine existence.

Schematic representations of the process whereby the initial pair of tubes forms a single tube with subsequent twisting and formation of chambers and very complex vascular structures (some of which become atretic, whereas others become dominant) can help in understanding spatial relationships and the reasons specific lesions develop. The lymphatic system, which develops in a similar time line, is seen initially somewhat later than the cardiovascular system. The lymphatics have connections with the venous side of the developing cardiovascular system. Malformations of the cardiovascular system occur in approximately 7.5 in 1,000 live births. The critical period for teratogenic effects ends relatively early in the intrauterine period, but the process of formation is so complex that a multitude of possibilities for maldevelopment exists. The degree of severity varies considerably.

Some structural malformations, such as the patent foramen ovale type of atrial septal defect, may be functional only when another pathologic condition exists. The patent ductus arteriosus as a pathologic entity occurs when closure fails after birth; in the fetal state, the patent ductus arteriosus is normal. Use of nonsteroidal antiinflammatory agents by pregnant women in the third trimester can cause premature closure of the ductus arteriosus and cardiac failure. Early malrotation of the fused cardiac tubes can result in dextrocardia, which can occur with an otherwise normal heart and great vessel structures and may not be a clinical problem if complete situs inversus of the viscera also is present. Dextrocardia without situs inversus is often a major problem because of a tendency for associated complex intrinsic abnormalities.

Intracardiac malformations, such as septal defects, are very common, especially in the ventricle. Complex problems, with formation of the great vessels evolving from an inappropriate partitioning of the truncus arteriosus, are also fairly common. Coarctation of the aortic arch is an example of a malformation that may be some distance from the heart itself. Manifestations of malformations can occur in utero and are thought in some instances to result in infants who are large for gestational age. In severe and relatively rare instances, they can produce a form of nonimmune hydrops fetalis.

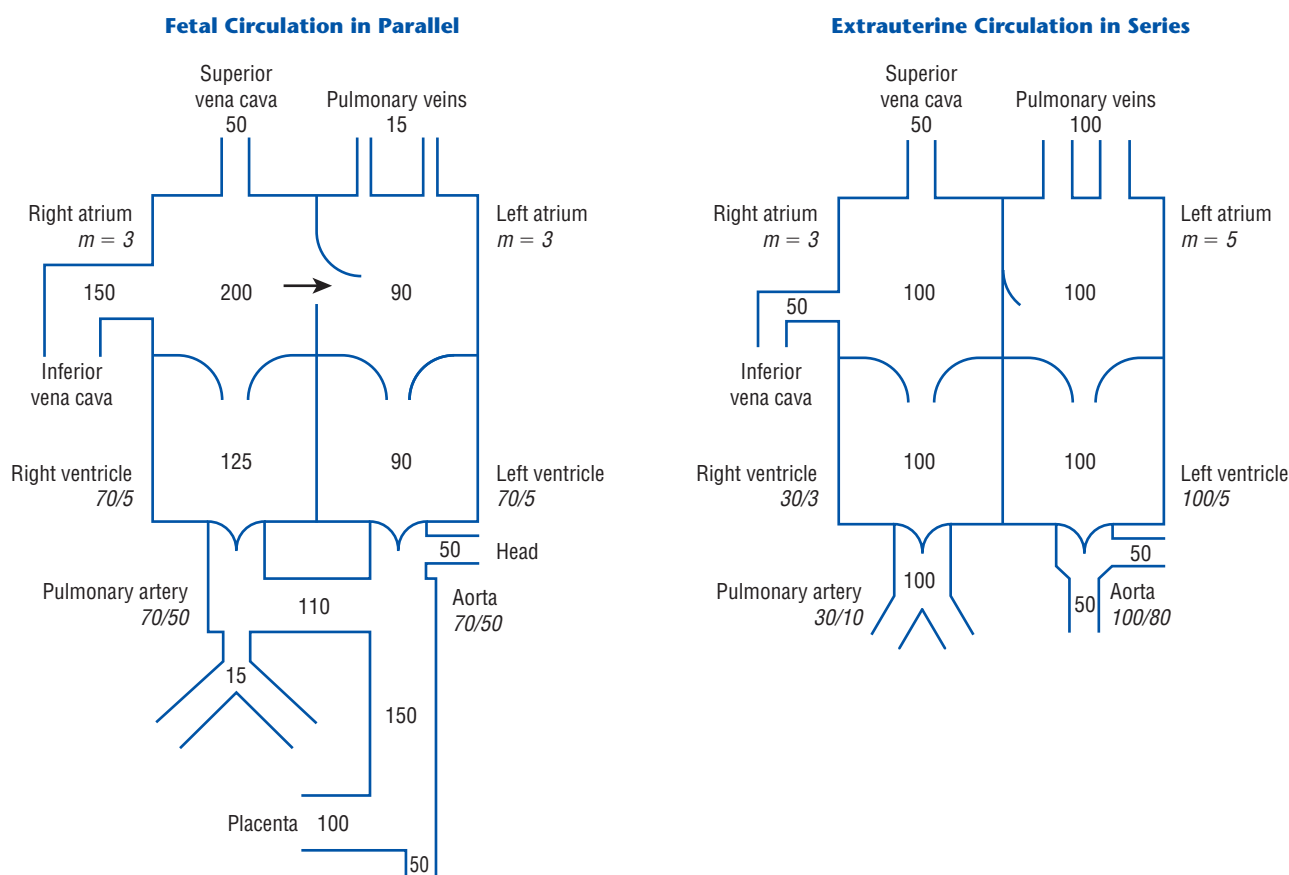

The physiologic aspects of cardiac function in the fetus are basically different from those in the infant, child, and adult. The fetal circulation has several parallel circuits, rather than the series (or sequential) circuitry that is established after the closure of physiologic shunts during or shortly after birth (Figure 80-5). The fetal heart has lower myocardial compliance and ventricular ability to increase stroke work. Increases in heart rate or filling pressure cause little increase in cardiac output.

The pediatrician, pediatric cardiologist, and neonatologist are increasingly becoming involved with cardiac dysfunction before birth. The evaluation of fetal well-being includes cardiac status, with the result that problems such as cardiac arrhythmia or cardiac failure can be detected in utero. Fetal echocardiography can detect specific structural defects, with the interval from 18 to 24 weeks optimum for such an evaluation. Pregnant women who are healthy are admitted to hospitals for treatment of fetal cardiovascular disease; use of antiarrhythmic drugs in the pregnant woman to treat fetal cardiac arrhythmias is an example of fetal treatment by way of the maternal and placental circulations. Medications used to treat fetal arrhythmias in utero may include digoxin, propranolol, flecainide, sotalol, or amiodarone.

### **Musculoskeletal System**

Formation of the musculoskeletal structures becomes apparent in the embryo by at least the fourth week, when limb buds (first the upper and then the lower) become obvious. Muscle structures originate from mesoderm, much of which arises directly from the somites. Bone evolves from mesoderm that undergoes a process of chondrification. Cardiac muscle and other smooth muscles have a different origin in the splanchnic mesoderm of the primitive gastrointestinal tract. The origin of some muscles, such as those of the iris and extrinsic eye, is unclear. The limb buds elongate while forming bone and large-muscle masses. A process of rotation and growth, in which upper and lower extremities rotate in different directions, results in the muscle groupings and dermatome patterns of the child and adult.

Malformations of the limbs are relatively common; otherwise, skeletal and muscular abnormalities are rare. The physician providing newborn care is often struck by the significant attention paid by parents to the extremities, particularly the hands, of newborns. For this reason, relatively minor defects can have major emotional significance. Polydactyly and syndactyly are among the more common human malformations.

**Figure 80-5** In the fetus, blood follows several routes, with a small portion going to the lungs. Oxygenated and nonoxygenated blood is admixed in the fetus, and the placenta serves as the fetal organ of respiration. The risk for expression of cardiovascular disease differs before and after birth because of changes in structure and flow. The numbers inside the diagram represent blood flow (rate), and numbers in italics represent pressure. (Adapted from Flanagan MF, Yeager SB, Weindling SN. Cardiac disease. In: Avery GB, Fletcher MA, MacDonald MG, eds. *Avery's Neonatology: Pathophysiology and Management in the Newborn*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999. Reprinted by permission.)

Many limb abnormalities are genetic in origin, but some malformations result from genetic predisposition interacting with environmental factors. The thalidomide deformities were a specific and perhaps relatively isolated example of limb teratogenesis. Sirenomelia, or caudal regression syndrome, is pathognomonic for poorly controlled maternal diabetes.

### Gastrointestinal System

The alimentary tract, developing from a primitive anlage seen initially at the fourth week, has 3 main divisions: foregut, midgut, and hindgut. Each of these divisions has its own specific blood supply in the celiac, superior mesenteric, and inferior mesenteric arteries. Because development of each tract can be traced, abnormalities of the individual divisions are seen. The foregut, from the pharynx to the insertion of the common bile duct, develops into various structures, including the intestine and the liver and pancreas. Midgut structures include all the small intestines (except for the duodenum proximal to the insertion of the common bile duct) plus the cecum, the appendix, the ascending colon, and approximately two-thirds of

the proximal transverse colon. The midgut structures go through a complex rotation during development, whereby an initial loop develops outside the fetal abdomen and rotates approximately 90 degrees at that time. At approximately the 10th week, these midgut intestinal structures return to the abdomen and go through a further complex rotation of 180 degrees, leading to the final anatomic relationships of the intestine. Hindgut structures include the transverse, descending, and sigmoid colon and rectum through the final portion of the anal canal, which develops from an anal pit. The cloaca (the early expanded end of the hindgut) and tissues of other origin form the perineal structures.

Alimentary tract malformations are fairly common and often are associated with other anomalies. The foregut has an initial tracheoesophageal common origin, with subsequent separation. Tracheoesophageal fistulas resulting from errors in formation of the tracheoesophageal septum occur in 4 basic patterns; early detection is important to prevent extensive aspiration pneumonitis. Errors of midgut development and malrotation lead to many problems, the most

spectacular of which is the lack of return of the bowel to the abdominal cavity, with a resultant omphalocele. Other malrotation presentations include acute intestinal obstruction and ischemia in utero or at varying lengths of time after birth, often after initial feedings. Malformations of the intestinal tube in the form of stenosis, duplication, or atresia are of unclear origin but may result from problems with recanalization or a compromised mesenteric vascular supply. Hindgut malformation occurs most commonly at the most distal portion, resulting in atresia, stenosis, membranous obstruction, or imperforate anus. Many other intestinal malformations can be seen. Of special interest is Meckel diverticulum (an outpouching in the ileum), representing the remnant of the yolk stalk.

### Respiratory System

Respiratory system formation begins at approximately 26 days and goes on long after birth. Initial cell lines arise on the floor of the primitive pharynx and produce a laryngotracheal tube. Endoderm of this tube becomes the lining and glands of the lower respiratory system; connective tissue and cartilage of the respiratory system arise from splanchnic mesoderm. Further growth of the endotracheal tube results in 2 lung buds that divide further into 2 sections on the left and 3 on the right; these correspond to the adult lobes. Branching continues after this point to form the pulmonary segments. Approximately 5 to 7 weeks after fertilization, a pseudoglandular period exists during which major growth of the bronchi and terminal bronchioles occurs.

During the canalicular period beginning at 13 weeks and continuing to approximately 25 weeks, bronchioles and alveolar ducts develop, and significant vascularization occurs. From 24 weeks until birth, terminal sacs arise and become alveoli. These sacs are initially lined by a cuboidal epithelium, which changes to a squamous form at approximately 26 weeks' gestation. Alveolar development continues through early childhood. The association of the development with the threshold of extrauterine viability is obvious.

Surfactant is not produced until alveoli are formed. Complex cell types lining the alveoli have been described. A vacuolated cell, the type 2 pneumocyte, seems to have a secretory function and to be involved in alveolar stabilization through the elaboration of surfactant.

Anatomic malformations of the pulmonary parenchyma are unusual but include many dysplastic and cystic abnormalities. (See Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.) Because of the nature of fetal respiration, in which gas exchange is not occurring in the lung, these abnormalities are usually not problematic until after birth. Abnormalities of the diaphragm, the most common of which is diaphragmatic hernia, are most frequently seen on the left and often are associated with severe restriction of lung development on 1 or both sides. Some infants who have diaphragmatic hernia exhibit persistent pulmonary hypertension, a complication that includes increased vascular resistance similar to that seen in the fetus.

The pediatrician confronts respiratory problems closely related to the formative and maturational

status of the lung. For example, at 22 to 25 weeks' gestation, alveolar formation may not be advanced to the point of being able to support life, even when exogenous surfactant, mechanical ventilation, and other interventions of present-day neonatal intensive care are used. This situation is encountered in the extremely low-birth-weight infant, or *micropremie*, and is basically a problem of pulmonary immaturity rather than prematurity. Whether respiratory distress syndrome is present after the birth of a premature baby depends largely on the functional cellular maturity of the infant's lungs. Antenatal treatment includes the use of corticosteroids to enhance fetal pulmonary maturity in pregnancies at risk for preterm delivery. Administration of a single course of corticosteroids is recommended for the pregnant woman at risk for preterm delivery, between 24 and 34 weeks' gestation. Postnatal treatment includes administration of exogenous surfactant until endogenous production occurs. (See Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.)

Prenatal exposure to air pollutants, including heavy metals, tobacco smoke, sulfur dioxide and particulate matter, and pesticides such as polychlorinated biphenyls and dichlorodiphenyltrichloroethane, are known to cause low birth weight, fetal growth restriction, and preterm birth, as well as malformations and neurocognitive deficits. There is a causal relationship between exposure to ambient air pollutants and adverse effects on lung function development. Both reversible deficits of lung function and chronically reduced lung growth rates and lower lung function levels are associated with exposure to air pollution, with clearer relationships for particulates and traffic-related air pollution. A causal relationship has also been shown between exposure to air pollution and aggravation of asthma (mainly resulting from exposure to particulate matter and ozone), as has a causal link between increased prevalence and incidence of cough and bronchitis resulting from particulate exposure. Maternal smoking during pregnancy is associated with poor fetal development. Exposure to secondhand smoke (also referred to as environmental tobacco smoke) during pregnancy might also result in a higher risk for poor fetal development (ie, reduced birth weight and birth length), reduced lung function, respiratory illnesses (eg, asthma), and cognitive deficits (eg, impaired speech, language skills, and intelligence).

### Hematopoietic System

Initial red blood cell formation is seen as early as day 14 after conception, when cells containing embryonic hemoglobin arise from the endothelium of primitive vessels of the yolk sac. Hematopoiesis within the embryo begins in the liver at approximately the sixth week, and this remains the most active site during the early part of the fetal life span. The bone marrow assumes the primary role at approximately the sixth month, and other sites, especially the spleen and lymph nodes, play a contributory role.

Fetal hemoglobin (HbF) predominates for much of intrauterine existence and under normal circumstances is seen to a small degree in early infancy. Beginning at

approximately the third month, some hemoglobin A (HbA) is present (5%–10%), and the proportion of HbA to HbF increases rapidly from approximately 35 weeks to term, when blood is approximately 50% to 65% HbF. HbF has an increased oxygen affinity compared with HbA, probably the result of a differing action of 2,3-diphosphoglycerate, which facilitates oxygen saturation in the intrauterine environment. Blood group antigens are familial in their determination and can be identified as early as the second month of fetal life. Platelets also are seen at approximately the second month. The presence of hematopoietic abnormalities is important for the physician to recognize. Certain hemoglobinopathies may result in intrauterine disease.  $\alpha$ -Thalassemia results in hemoglobin Bart (tetrameric  $\gamma$ -chains), which has a very high oxygen affinity, resulting in intrauterine distress from tissue hypoxia and non-immune hydrops fetalis. Several other significant hemoglobinopathies (eg, homozygous and heterozygous  $\beta$ -thalassemia) and structurally abnormal hemoglobins have been identified, such as HbS and HbC. PCR analysis of DNA from samples obtained by amniocentesis is possible. Hemolytic anemia that results from maternal–fetal blood group incompatibilities and transplacental passage of antibody is an immune disease; however, it has a marked effect on hematopoiesis, resulting in erythroblastosis fetalis and extensive proliferation of hematopoietic tissue. Fetal thrombocytopenia may be primarily of fetal origin, or it may be associated with some form of extrinsic agent or process, such as immune antibody of maternal origin or intrauterine infection. Many fetal intrauterine hematologic manifestations are part of disease processes involving other systems.

Middle cerebral artery Doppler velocimetry, amniocentesis, and PUBS are clinically useful in fetal hematologic disorders. Middle cerebral artery velocimetry is used to noninvasively diagnose fetal anemia, as seen, for example, with alloimmunization. PUBS can be used to diagnose thrombocytopenia and for platelet transfusions or exchange transfusions in the fetus with severe anemia caused by blood group alloimmunization.

### Immune System

Immune system components function very early in fetal life, with some parts present as early as the eighth week and with a total rudimentary system capability by the 12th week. The cellular immune system originates in liver or spleen stem cells that migrate to the thymus at approximately the eighth week. These T cells enter the bloodstream and are distributed to the body, mainly to the lymph nodes and spleen. The antibody immune system generates IgM in lymphoid tissues as early as the 11th week and IgG at approximately the 12th week. IgA, IgD, and IgE are seen in the fetus in small amounts toward the end of pregnancy. Current thinking suggests that specific immunoglobulin synthesis occurs in stem cells or B cells. Passive transfer of maternal antibody has been demonstrated very early in fetal life. Maternal IgG is detectable as early as the 40th

day, and practically all cord IgG is maternal in origin, arising from both passive and active enzymatic transplacental passage. IgM is not transferred passively. The complement system has some fractions present during the embryonic period at the eighth week, and by 12 to 14 weeks' gestation a considerable complement fraction is present. Malformations of the fetal immune system, of either familial or developmental origin, have been described and have contributed to an understanding of the adult system.

Abnormalities are thought to exist in all parts of the immune system, and physicians should understand the basic possibilities because of the fetal and neonatal diseases that result. Fetal graft-versus-host reactions have been documented after intrauterine transfusions. Congenital infections activate the immune system, with an increased cord IgM level possibly being evidence of such infections. Fetal IgM is usually not present until the third trimester. At term, IgM and IgA are detectable but at levels much lower than in the adult. Transplacental antibody passage with effects on the fetus, as seen in alloimmunization (erythroblastosis fetalis), is the classic clinical example of fetal disease resulting from activation of a maternal immune system response.

### Urogenital System

A close interrelationship exists between the development of 2 basic systems: the urinary (or excretory) system and the genital (or reproductive) system. The human embryo has 3 separate excretory organs: the pronephros, the mesonephros, and the metanephros. The metanephros appears at approximately the fifth week after fertilization, functions 2 to 3 weeks later, and remains as the permanent kidneys. The other 2 systems involute, with the mesonephros remaining as a few ducts in the male genital tract and as a vestigial remnant in the female genital tract. The final excretory system has 2 main divisions. The entire collecting system from the kidney to the bladder originates from the ureteric bud; nephrons arise from the mesodermic-metanephric mass. The kidney tissue appears originally in the early pelvic region and ascends into the abdomen. The bladder develops from the urogenital sinus and splanchnic mesenchyme. Excretory system function is present by approximately the ninth week; theoretically, contributions to amniotic fluid are possible at this time and become the major component later in gestation.

The prospective phenotype of the genital system is determined at fertilization. However, an indifferent stage of genital development exists, ending at approximately the seventh week, with the gonads showing specific sexual characteristics. By the 12th week after fertilization, the genitals are distinctly male or female. The Y chromosome seems to be responsible for the differentiation of testes. Masculinizing hormones from the testes stimulate development of mesonephric ducts into genital components and result in the external genitals forming a penis and scrotum. Feminization of the external genitalia seemingly occurs in the absence of androgens. Gonadal tissue has its origin in the lateral abdominal wall,

with the testes descending into the scrotum late in fetal life.

Malformations of the urogenital system are relatively common and result in a myriad of morphologic and microscopic manifestations. Some entities, such as renal agenesis, result in intrauterine manifestations, including oligohydramnios, and in morphologic changes in the fetus. Other problems may occur in the immediate neonatal period. For example, renal abnormalities that result in cystic lesions of the kidneys initially may be detected in the newborn period as abdominal masses found at physical examination or as abnormalities in renal function. Malformations in the vascular supply to the kidneys or the collecting system result in congenital problems such as obstructive uropathy that predispose the person to renal disease, occurring in infancy and childhood. Ultrasound evaluation of the fetal collecting system may demonstrate findings consistent with dilation that does not persist. Fetal observations should be evaluated after birth. Malformations arising from problems of formation of the urogenital sinus and urachus may be severe, as in extrophy of the bladder or, less obviously, as in fistulas between perineal structures.

Abnormalities of kidney function can develop in utero. Maternal exposure to angiotensin-converting enzyme inhibitors in the second and third trimesters can cause renal failure and severe oligohydramnios without structural abnormalities.

Malformations of the genitals also can be complex in origin; those caused by errors in the sex-determining mechanism can result in hermaphrodites but are rare. Errors in sexual differentiation, producing pseudohermaphrodites, are somewhat more common. The presence of neonatal ambiguous genitalia is a true medical emergency, requiring immediate evaluation. Congenital adrenal hyperplasia, which is characterized by fetal androgen excess and masculinization of the female fetus, accompanied by a deficiency of cortisol and leading to salt wasting and shock, is a possible cause. (See Chapter 58, Fluids, Electrolytes, and Acid-Base Composition; and Chapter 243, Disorders of Sex Development.) Exposures to potential endocrine disruptors, naturally occurring compounds, or human-made substances that may mimic or interfere with normal hormonal function, have been linked with developmental, reproductive (fertility; genitourinary anomalies; cancer [diethylstilbestrol]), neural, immune, and other conditions. Some environmental endocrine-disrupting chemicals, such as the pesticide dichlorodiphenyltrichloroethane, dioxins, and polychlorinated biphenyls, are highly persistent and slow to degrade in the environment, making them potentially hazardous over an extended period of time.

### Special Considerations

Certain situations of fetal formation and malformation deserve special mention. The special senses, specifically those of the eyes and ears, are very sensitive to teratogenic activity and result in profound effects on the developing infant and child. Eye formation begins at the fourth week and proceeds very rapidly,

especially through the sixth week. Malformations of the eye and ear may be associated with errors in genetic material; some syndromic conditions have readily identifiable eye and ear malformation patterns. Intrauterine infections, particularly rubella, can affect the eye and inner ear. CMV is a common cause of congenital deafness. Errors in position or morphology of the external ear often are associated with other malformations.

Malformations of the face and palate are of major concern. These malformations have their origin in the embryonic branchial apparatus from which the face, pharynx, and attendant structures develop. Cleft lip often is associated with cleft palate but arises from distinctly different origins. Cleft lip is often recognizable on second-trimester ultrasound, but prenatal diagnosis of cleft palate remains elusive. Three-dimensional ultrasound holds promise for the diagnosis of cleft palate. Difficulties in these areas are probably of mixed genetic and environmental cause. The branchial arch merging in the formation of palate structures is most susceptible to teratogenic factors between 6 and 10 weeks' gestation.

### Fetus, Mother, and Family

The fetus influences the mother and family physically and emotionally. Although expectations regarding conception and childbearing vary, the most positive situation is one of physical reproductive readiness and an anticipated pregnancy. Psychological factors involved in the decision to become pregnant are extremely complex and heavily influenced by societal mores and values. More than 50% of all pregnancies in the United States, and a much higher portion of pregnancies in teenagers and unmarried women, are unanticipated, but not necessarily unwanted, at conception. Psychosocial situations that detract from optimal health before conception should be interpreted as the beginning of potential fetal risk.

Many maternal and familial situations of unfortunate familiarity to the physician provide a bad start for the pregnancy; a common example is pregnancy in the younger adolescent, who is both physically and emotionally immature and who may well not have a stable interpersonal relationship with her male partner. Post-conceptual factors interact after fertilization occurs, with a progression of biochemical, physical, and emotional changes that influence the mother, father, and family. Poverty has a profound effect on the physical, emotional, and cognitive well-being of children, adolescents, and adults. These effects can be mitigated by health and social programs such as Medicaid and the Special Supplemental Nutrition Program for Women, Infants, and Children.

These postconceptual changes, some subtle and some not, permanently alter the parents' lifestyle. New situations demand behavioral adaptations and a process of coping. If the coping process is successful, then major developmental progress has been made, especially by the mother; such is usually true to a lesser extent in the father and to varying degrees in people further removed. However, if attitudes and the coping process are unsatisfactory, then adoption or abortion may be considered.

The first missed menstrual period, an overt sign of change to many women, does not occur until after the stage of the dividing zygote is essentially complete. By the time of the second missed menstrual period, the embryonic stage is one-half over (see Figure 80-3). Although the zygotic stage is relatively unaffected by teratogens, the embryonic stage is one of very high risk. Maternal and familial habits potentially injurious to the fetus are difficult to alter under any circumstances, and of course altering circumstances is impossible when the mother does not yet know that she is pregnant. Pregnancy is often not confirmed in the present medical system until after the second missed menstrual period.

The customary use of trimesters as a means of dividing pregnancy into 3 intervals of equal length of particular personal or medical significance is considered imprecise by obstetricians and is discouraged for clinical situations. Nonetheless, the trimester concept remains in common use in discussions of the progression of pregnancy and its influence.

The first trimester may be the most important phase of adjustment to the fetal presence. Many women experience physical symptoms such as fatigue, nausea, and headache, as well as changes in emotional status. The second trimester is usually marked by less overt signs of physical and emotional adjustment and discomfort. System development in the fetus is basically complete, and major growth is occurring. This development leads to the phenomenon of quickening, when a woman feels fetal movements for the first time at approximately weeks 18 to 20 in the primigravida; in the multigravida, such movement may be felt 1 to 2 weeks earlier. Quickening undoubtedly represents a major milestone in the relationship between a woman and her fetus. This sign is the first overt or direct sign of independent fetal activity. Awareness of fetal movement can provide some information about gestational age. For some women, it also serves as a milestone after which abortion is an even more difficult choice.

The third trimester is marked by an acceleration of the fetal alteration of lifestyle. Maternal physical activity, previously undertaken easily, may become increasingly difficult. Sexual activity between parents may be subject to changes or even cessation. Preparation for delivery becomes more of a part of everyday life; childbirth education, financial planning, and other aspects of preparation and emotional adjustment should be in progress. Ideally, a first appointment with the pediatrician would occur at this time.

### Fetus, Health Professional, and Society

Great concern over the influence of factors such as smoking, alcohol consumption, radiation, and pesticides on the fetus is supported by many studies, and research continues to expand the database. Societies that advocate preconception care and the introduction of employment, nutritional, and lifestyle changes for women as soon as they miss a period (or preferably before conception) are surely enlightened in

their advocacy of improved fetal and pregnancy outcomes.

Amniocentesis, chorionic villus sampling, and percutaneous umbilical cord sampling represent procedures of major interest to individuals and society because they enable physicians to detect conditions incompatible with what is considered normal human existence. These procedures allow families to prepare for the birth of an infant who may have special needs or requirements or to make the difficult and personal decision to terminate a pregnancy. Moral and ethical concerns over these procedures are related to those associated with abortion generally. The debate over legalized abortion has brought to the fore concerns about the legal and interpersonal status of the fetus. Health professionals are embroiled in this debate, especially over whether a physician of perinatal medicine can personally oppose abortion and therefore not mention all alternatives to patients.

*Viability*, or the capability of a fetus to assume an independent extrauterine existence, is a concept that demands attention and thought. Research shows that 23 weeks from the last menstrual period is the time at which some fetuses, if born into an environment in which neonatal intensive care is available, can survive. The role of the family in decision making, especially with regard to the extent of intervention for a baby born at the threshold of viability, is a matter of great interest. In particular, the frequency of somber modes of survival needs to be presented sensitively. Parents and pediatricians have advocated that for premature infants born between 23 and 25 weeks' gestation, parental wishes should be recognized and followed.

The physician must be aware of the close approximation of potential viability and gestation limits on legal abortion in the context of significant variations in clinical estimates of fetal age. The Supreme Court decision (*Roe v Wade*) has been interpreted to support legal abortion, although state laws vary with respect to gestational age limits. Menstrual dating by history and physical examination is only accurate within a range of 2 to 4 weeks. Confirmation of pregnancy dating by ultrasound examination improves the precision of dating to approximately 10%, so that a variation of 10 to 14 days is still possible in the second trimester. Ultrasound dating in the first trimester is associated with the smallest margin of error.

## Chapter 81

# ASSISTED REPRODUCTIVE TECHNOLOGIES, MULTIPLE BIRTHS, AND PREGNANCY OUTCOMES

Christie J. Bruno, DO; Edith A. McCarthy, MD;  
Peter A. M. Auld, MD; James A. Grifo, MD, PhD

## INTRODUCTION

The decision to bring a child into the world is a momentous one. For some people, reproductive medicine may be necessary to realize this goal. Infertility rates in industrialized countries have risen for 3 decades, mostly as a result of couples delaying childbirth. Infertility is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. This affects approximately 15% of couples in the United States. Infertility arises from a male etiology in 8%, female etiology in 37%, and a combination of the 2 in 35%. The Centers for Disease Control and Prevention (CDC) report that approximately 12% of women of reproductive age (ie, 7.4 million) have had an infertility-related medical visit within the previous year, and an additional 10% have received infertility services at some time in their lives. Additional CDC data demonstrates infertility in 7.5% of men younger than age 45. Up to 4.7 million men have sought evaluation from a fertility specialist. Typically 18% of men evaluated are diagnosed with a fertility problem. Assisted reproductive technology (ART) has been used in the United States since 1981 to help couples achieve pregnancy, most commonly through ovulation induction and the transfer of fertilized human eggs into a woman's uterus (in vitro fertilization). In fact, over 1% of all infants born in the United States every year are conceived using ART. Assisted reproductive technology includes all fertility treatments in which both eggs and sperm are manipulated. Assisted reproductive technology (ART) procedures most commonly involve surgically removing eggs from a woman's ovaries, combining them with sperm in the laboratory, and returning them to the woman's body or donating them to another woman. The types of ART are in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT). The 2 procedures utilized during IVF are ICSI, intracytoplasmic sperm injection, and PGD, preimplantation genetic diagnosis. PGD is a technique that combines molecular genetics and ART, allowing clinicians to identify various genetic diseases in the embryo prior to implantation. Intracytoplasmic sperm injection involves injection of a single sperm directly into an egg; this procedure is commonly used to overcome male infertility problems. Deciding whether to undergo this expensive and time-consuming treatment can be difficult. Ninety-nine percent of ART cycles involve an IVF procedure of a woman hoping to bear a child; less than 1% involve a gestational carrier or surrogate. According to the CDC 2011 ART Success Rates Report,

151,923 ART cycles were performed at 451 reporting clinics in the United States during 2011, resulting in 30,211 live births. This is a decrease of 34.8% in the number of live births as compared to 2008. This results from fewer eggs being implanted during an IVF cycle, on average 2 eggs per cycle irrespective of procedure. This change in practice first recommended in 1998 by the Society for Assisted Reproductive Technology and the American Society for Reproductive Medicine (ASRM), has evolved from the recognition of poorer outcomes for triplet and higher order gestations.

When taking a child's history, the health professional should include the history of the perinatal course, whether a history of infertility exists, and if any assistive measures were used to achieve this or previous pregnancies. In the instances when a multifetal pregnancy occurred, the discussion should include whether any associated fetal or neonatal losses occurred. This information is sensitive as a given family may not want others to know about their fertility issues or the nonmaternity or paternity of their child. Given that this issue is sensitive for many parents, such information may not be divulged spontaneously. The physician must probe gently to elicit this information since a further concern is the increased risk of congenital malformations with ART. For this reason, it is important for those caring for a child to know the means of conception. For example, malformations of the eye, head and neck, heart, and genitourinary system are increased with ART, and even more so with multiple gestation pregnancies.

Our understanding of the outcomes over the life course and into adulthood for children born through assisted conception is evolving. Overall, health and developmental outcomes seem to be comparable with young adults who were naturally conceived although there are concerns about cardiometabolic risks and higher rates of psychological disorders in individuals born through ART.

## TREATMENT OF INFERTILITY

### Artificial Insemination With Donor Sperm and Intrauterine Insemination

Artificial insemination (AI) represents the oldest form of assisted reproduction, with attempts dating back to Princess Joana of Portugal, wife of King Henry IV of Castile, circa 1455. Efforts to develop practical methods for AI began in Russia in 1899. Intrauterine insemination (IUI), a technique involving the injection of collected sperm-containing semen into a woman to cause pregnancy, is used in cases of infertility or impotence or as a means by which a woman without a partner may become pregnant. Approximately 80,000 procedures using donor sperm are performed each year, resulting in the births of 30,000 babies. For many years, artificial insemination with donor sperm (AID) was the only available treatment for male factor infertility. Today, IUI is indicated also for idiopathic or unexplained infertility, to bypass cervical abnormalities, and to offer lesbian couples the option of childbirth. When IUI is combined with ovarian hyperstimulation, the chance of achieving a pregnancy is increased compared with IUI alone.

### In Vitro Fertilization and Related Assisted Reproductive Technologies

In vitro fertilization (IVF), which accounts for 99% of ART procedures performed by fertility clinics in the United States, is an outpatient procedure that uses ovulation induction, ultrasound-guided oocyte retrieval techniques followed by an in vitro fertilization procedure that uses sperm from the male partner or another donor, and transcervical embryo transfer 2 to 3 days after fertilization of the retrieved eggs. The procedure can be performed under sedation without the need for general anesthesia. Although IVF was originally developed to treat women who had absent or irreparably damaged fallopian tubes, use of this procedure has since expanded to treat many other causes of infertility, including tubal obstruction, pelvic adhesions, endometriosis, male factor infertility, and immunologic or idiopathic infertility.

A woman's age is the single most important variable affecting success rates after IVF. Pregnancy rates drop precipitously and miscarriage rates rise in women older than 40 years because of a lack of ovarian reserve (declining number of eggs in the aging female ovary). Low ovarian reserve decreases a woman's chances for conception. To optimize success rates, traditionally many IVF programs in the United States have transferred relatively high numbers of embryos with the hope that at least 1 will result in a pregnancy. The 2008 National Summary and Fertility Clinic Reports of the CDC showed that 38% of ART cycles involved the transfer of 3 or more embryos. The result has been an unprecedented increase in the incidence of multiple births. In the United States, the number of twin births has risen nearly 2-fold between 1971 and 2009, the year with the highest recorded number of twin births. The rates of triplet and higher order births also increased 6.7-fold, reaching a peak in 1998. Over the past 2 decades there has been a 29% reduction in triplet and higher order birth. However, in 2011, 3.5% of live births were multiple gestations, double the incidence in 1971. To lessen the incidence of multiple births and the associated risks of gestational diabetes, preeclampsia, and prematurity, among others, in 2013 the ASRM updated the recommended number of transferred embryos per IVF cycle. Based on the new recommendations, for patients younger than 35 years with a favorable prognosis, a single embryo transfer should occur. Following this recommendation, a decrease in higher order multiple births has already been demonstrated. This is similar to the practice of many European and international communities. In fact, international research supports that single embryo transfer reduces the risk of perinatal mortality with IVF. Detailed information regarding the current status of ART is reviewed annually in the CDC publication *Mortality and Morbidity Weekly Review Surveillance Summaries*.

### Ovulation Induction

Ovulation induction (OI), which uses ovary-stimulating drugs, has been used traditionally for women who have anovulation and oligoovulation, for whom it improves the chance for conception each month by increasing the number of eggs that will ovulate. OI

medications may also control the timing of ovulation, so that intercourse, IUI, and IVF can be scheduled to achieve pregnancy. However because of the uncontrolled nature of OI, there is significantly increased risk of twin and higher order multiple pregnancies. As a result, many states have limited the number of OI cycles prior to IVF initiation, because IVF can more predictably result in a singleton pregnancy. It is important to note that a serious complication of OI is ovarian hyperstimulation syndrome (OHSS). The presentation of OHSS may range from mild to severe with gastrointestinal symptoms, bloating, and weight gain. As symptoms progress, a patient may experience shortness of breath from pulmonary edema and may develop blood clots. These are all attributable to a varying degree of ovarian enlargement.

### Intracytoplasmic Sperm Injection

Representing a true revolution in assisted reproduction, intracytoplasmic sperm injection (ICSI) involves the insertion of a single spermatozoon, selected by a trained embryologist based on its morphology and motility, into the cytoplasm of an oocyte, thereby bypassing all of the inherent obstacles for penetrating the oocyte, such as the zona pellucida.

ICSI is currently the treatment of choice for male factor infertility and for couples who have experienced previous IVF failures or low yield of eggs at egg retrieval. Male factor infertility accounts for nearly one-third of all infertile couples and is caused by low sperm count, poor sperm motility, or poor sperm morphology.

## PREGNANCY RATES AFTER IN VITRO FERTILIZATION

Approximately 20% of IVF pregnancies are lost, most as first-trimester spontaneous abortions. The rate of loss after IVF exceeds that for spontaneous conceptions for several reasons, including the adverse effect of high ratios of estradiol to progesterone on the endometrium, an increased incidence of genetically abnormal oocytes and embryos after OI in an inherently higher-risk population, and a higher risk for ectopic pregnancy. More than 50% of IVF pregnancies are lost in women older than age 40. For older women, diminished ovarian reserve, a condition characterized by a low ovarian egg reserve or impaired development of existing eggs, often accounts for this significantly decreased success rate. Strategies to improve success rates in this population include DHEA supplementation to increase the quantity and quality of eggs and embryos in addition to the use of donor eggs. Although IVF success rates are increased in older women with the use of donor eggs, concerns exist with regard to the basic principles of medical ethics. Specific concerns pertain to autonomy of the egg donor (coercion and uninformed consent) and equality (those who can afford to pay for egg donors are more likely to find a donor).

Of ART cycles in 2008 that used fresh nondonor eggs or embryos, 35% resulted in clinical pregnancy. Approximately 81% of the pregnancies resulted in a

live birth (about 56% singleton birth and 26% multiple birth); about 18% of pregnancies resulted in miscarriage, stillbirth, induced abortion, or maternal death prior to birth.

## MAKING THE DIAGNOSIS OF INFERTILITY

A couple is considered infertile only after unprotected, well-timed intercourse for more than 12 months has failed to result in pregnancy. This rule does not apply to couples when either partner has a history of fertility-related problems. *Primary infertility* refers to those couples who have not become pregnant after at least 12 months of unprotected intercourse; *secondary infertility* refers to couples who have been pregnant at least once, but are not able to get pregnant at present time. Infertility, or a reduced potential for pregnancy, is distinguished from sterility, in which no chance for pregnancy exists. Most childless couples younger than 40 years who are having problems conceiving are infertile but not sterile.

Reproductive endocrinologists attempt to determine the cause of infertility and counsel the infertile couple about realistic expectations and their prognosis for future fertility. Oversimplification of success stories of ART as reported by mass media has raised patient expectations to new, and occasionally insurmountable heights.

The most common causes of infertility are listed in Table 81-1. The cause of infertility is determined by performing a basic infertility evaluation, which includes taking a history and performing a physical examination, semen analysis, and blood tests that include follicle-stimulating hormone, luteinizing hormone, prolactin, testosterone, estradiol, progesterone, 17-OH progesterone, thyroxine, thyroid-stimulating hormone, lupus anticoagulant, anticardiolipin, and complete blood count. In addition, anti-Müllerian hormone assay has become utilized more recently as a more precise test of ovarian reserve. Fragile X testing must also be

**Table 81-1** Causes of Infertility

CAUSES OF INFERTILITY	PERCENT
Male factor	19
Multiple factors, women and men	28 (13% female factors only)
Tubal factor	13
Multiple factors, women only	12.3
Unexplained cause	10
Diminished ovarian reserve	9
Endometriosis	6
Other cause	7
Ovulatory dysfunction	6

Atlanta, GA: DHHS; 2013. Available at: [www.cdc.gov/ART/ART2011/](http://www.cdc.gov/ART/ART2011/). Accessed May 20, 2014.

considered, since carrier status is a potential cause of female infertility. Hysterosalpingogram and laparoscopy are indicated only if necessary to evaluate the anatomy of the endometrial cavity of the uterus and the fallopian tubes.

### PERINATAL OUTCOMES AND NEONATAL ISSUES ASSOCIATED WITH ASSISTED REPRODUCTIVE TECHNOLOGIES

Although dramatic advances in reproductive technologies have offered new hope to childless couples and new opportunities to those who want to postpone childbearing, they also have raised concerns about the ultimate outcomes for infants conceived after fertility treatments such as IVF or ICSI. Parents who conceive after fertility treatments want to know if their children are at higher risk for health problems compared with children who were conceived naturally. Since the birth in 1978 of the first child conceived through the use of IVF, numerous scientific papers have been published on various aspects of IVF, but few reports address perinatal complications, with even fewer studies characterizing the long-term follow-up of children from IVF. In fact, the CDC reports results by state for ART on their Web site based on various modalities and success rates, but do not report long-term follow-up results. This seems to be secondary to a lack of centralized follow-up of ART offspring, since many smaller clinics are administering these therapies without adequate governmental supervision. Identified risks with ART include an increased risk for preterm or low birth weight, multiple gestation, major malformations, growth delay, developmental delay (psychomotor and cognitive), infant mortality, and postnatal health problems. The wide spectrum of clinical sequelae following assisted conception contributes to longer duration of birth hospitalizations and more rehospitalizations during the first 5 years of life and higher health care costs.

Concerns have also been raised regarding increased risks of genetic imprinting disorders, such as Beckwith-Wiedemann syndrome, childhood cancer, as well as cardiometabolic effects in adulthood with ART. Given these reported risks, health care providers face ethical dilemmas about whether families should know these remote risks prior to pursuing ART.

#### IVF and Outcomes

Although many studies have reported reassuring data, because of faults in methods used, study results are considered insufficient to conclude that IVF has no detrimental effect on conceived children's growth or motor and psychological development. Some investigators have not found increased risks for structural abnormalities in offspring from ART pregnancies, whereas others document increased rates of adverse infant outcomes, including higher rates of birth defects. Several recent systematic reviews and meta-analyses of published studies on the outcomes of

ART-assisted pregnancies are limited by the quality of the studies available for analyses. The nature of ART, however, is such that studies typically categorized as the highest quality (level 1 evidence)—randomized controlled clinical trials that compare one treatment strategy with another—have not been considered feasible or appropriate under current clinical practice standards. Consequently, most studies on which these meta-analyses and systematic reviews have been based are lower quality investigations such as controlled trials without randomization and prospective cohort or case-control studies (level 2 evidence) and descriptive studies (level 3 evidence).

Equally important are the risks of adverse pregnancy outcome that result in maternal morbidity, with the potential for a serious effect on fetal and neonatal health. The National Institutes of Health-sponsored FASTER Research Consortium has reported on the outcomes of over 36,000 pregnancies among its participating centers nationwide, noting that OI is associated with significantly increased risks for placental abruption, fetal loss after 24 weeks, and gestational diabetes. Women who are undergoing IVF experience significant increases in rates of gestational hypertension and preeclampsia, placental abnormalities (abruption, placenta previa), and cesarean delivery.

#### Congenital Malformations and Chromosomal Anomalies

There are ongoing concerns regarding the risk for birth defects among infants born as the result of ART. A recent systematic review and meta-analysis identified a 30% to 40% increase with ART in the risk of having a major birth defect resulting in the need for medical or surgical intervention. Although the studies used in this analysis all had some limitation, the analysis does provide some perspective on the increased potential for a significant birth defect among infants of ART pregnancies. The absolute risk of malformations, however, is low.

Significant concerns have been raised over the possibility of adverse effects resulting from the ICSI technique, such as chromosomal abnormalities, congenital malformations, and intellectual disability. Reported outcomes vary. A 2005 study in *Pediatrics* is reassuring for parents who conceived through ICSI or IVF. The findings indicate that the motor and cognitive development of children conceived through these methods is similar to that of naturally conceived children. A meta-analysis conducted by Lie et al assessed the limited data comparing outcomes from ICSI pregnancies with those from conventional IVF. The authors did not find additional risks of major birth defects with ICSI. Nouri et al found in a comparison of neonatal outcomes following pregnancies achieved through IVF or ICSI, that IVF pregnancies were more complicated, yet the neonatal outcomes were better than infants born from ICSI pregnancies. A larger, more comprehensive study conducted in South Australia evaluated perinatal outcomes following assisted conception from 1986 through 2002. Neonatal outcomes varied by ART method. Among singleton

pregnancies following IVF there were higher rates of stillbirth, low- (<2,500 g) and very low-birth-weight (<1,500 g), preterm (<37 weeks' gestation) and very preterm birth (<32 weeks gestation) and neonatal death (<29 days of age). Neonates born of ICSI pregnancies experienced fewer adverse outcomes in comparison with IVF neonates. Infants born from frozen embryos did not exhibit the pattern of adverse outcomes more common among ICSI infants, but were not protected from the sequelae associated with IVF outcomes, preterm birth and reduced birth weight. A notable finding among frozen embryo births was macrosomia among some of the infants. Overall, the underlying infertility status was an important factor in the risk of an adverse outcome.

### Multiple Births

The most common complication of IVF is failure to achieve a successful pregnancy. If pregnancy is achieved, then multiple gestation pregnancy and prematurity are further serious concerns. Since the 1970s, the national twin-birth rates have increased worldwide because of ART. Multifetal gestation may occur resulting from ovarian hyperstimulation from OI or the implantation of multiple embryos. Ovarian stimulation alone also increases the twinning rate from a spontaneous rate of 1.2% to 5.9%. Rates of identical twinning and triplet gestation are also increased. Voluntary guidelines regarding the number of IVF embryos implanted may explain the higher rates of multiple births in the United States as compared with other countries such as Britain, Finland, and Sweden, where regulations typically limit the number of embryos implanted to 1. In the United States, ASRM made the same recommendation for women younger than the age of 35 with a favorable prognosis for pregnancy.

Multifetal pregnancies are at increased risk for preterm delivery or miscarriage and have the potential for significant sequelae in the offspring, including in utero fetal death, low birth weight, and disability among survivors. In a 2003 study, major morbidity—defined as neonatal intensive care admission, surgical intervention, special needs, and delayed speech development—was apparently related to multiple gestation as opposed to ART itself. The risk for perinatal mortality and morbidity is 5-fold and 7-fold higher for twins and triplets, respectively. The average duration of a multifetal gestation decreases by approximately 3 weeks for each additional fetus: 37 weeks for twins, 33.5 weeks for triplets, and 31.5 weeks for quadruplets. This decrease has resulted in a significant debate within the reproductive medicine communities in North America and Europe about the appropriate number of embryos to implant and the role of multifetal reduction.

Multifetal pregnancy reduction (MFPR) offers an alternative to couples who have high-order multiple gestations but poses ethical and religious dilemmas for many couples. Data are limited regarding outcomes of multiple gestations with or without fetal or embryo reduction. However, reports have surfaced that outcomes for both the mother and infant after MFPR are improved. Reports comparing obstetrical

outcome data from quintuplets or quadruplets reduced to twins and nonreduced multiple births suggest that the obstetrical outcome of pregnancies after reduction is improved compared with the data from nonreduced pregnancies. The data regarding reduction from triplet to twin gestation also demonstrates generally improved outcomes. In theory, reduction from triplet to twin decreases the chance of a very early prematurity and short-term morbidity. However, MFPR is itself associated with a risk for preterm delivery and fetal loss, particularly if performed after 15 weeks' gestation.

The risk for multiple gestation may also be reduced by limiting the number of eggs or embryos transferred to 2 or 1 when egg or embryo quality is high. Unfortunately, many clinics continue to implant more than the recommended number of embryos in their patients in an effort to meet patient demands and achieve high success rates. Britain, Germany, Sweden, Switzerland, and other European countries have banned implanting more than 3 embryos in women who are undergoing IVF for fear of multiple pregnancies. In the United States, the ASRM has published guidelines to assist ART programs and prospective patients in determining the appropriate number of cleavage stage (2- to 3-day) embryos that should be implanted. These guidelines specify that women younger than age 35 with a good prognosis should consider only single embryo transfer and that no more than 2 should be transferred in this age group except under extraordinary circumstances. Women between the ages of 35 and 37 should receive 2 embryos unless they have a poor prognosis, in which case 3 embryos should be the maximum implanted.

### Growth and Development

The long-term outcomes of children born using IVF seem similar to those of naturally conceived children when assessing scholastic performance, congenital malformations, and neurologic and psychomotor development. A recent study by the University of Iowa Hospitals and Clinics demonstrated that children from IVF actually scored higher on standardized tests than their matched peers, suggesting that IVF does not have a negative effect on cognitive development.

The growth of children from IVF may lag behind that of naturally conceived children during the first 3 years of life. There may also be an increased incidence of respiratory diseases and diarrhea in the neonatal period. Reported developmental outcomes of children from IVF compared with naturally conceived children are conflicting. The most recent reports of the neurodevelopmental well being of children conceived through ICSI conclude that verbal, performance, and full-scale IQ at 5 and 8 years of age are comparable among a group of children conceived by ICSI and IVF and those conceived spontaneously.

Data on outcomes of pregnancies achieved using frozen-thawed and cryopreserved embryos suggest a slightly lower developmental index with frozen-thawed embryos, but the results were not adjusted for prematurity. Long-term outcomes for children conceived by ICSI using fresh or frozen-thawed surgically

retrieved spermatozoa are not known. However, both sources of sperm are equally efficacious in achieving conception.

### Psychosocial Effect and Family Functioning

An integral component of infertility care is the provision of counseling during the evaluation and treatment cycles. Although the body of literature regarding the mental health issues experienced by couples undergoing infertility treatment and their transition to parenthood is small and primarily women focused, the work continues to grow. In addition, interest has grown in the psychological outcomes for children who are products of reproductive technology related to parent-child relationships and parenting skills in IVF pregnancies and the potential effects of nongenetic parenting when pregnancy is achieved through the use of donor eggs or sperm. The existing literature is limited in that it tends to focus on the parenting relationships with healthy children. Little is known about the mental health issues and burdens faced by parents who have undergone fertility treatments, achieved a pregnancy, but had a sick or disabled child or experienced a fetal or neonatal loss of 1 or more babies in a multifetal pregnancy. Recent reports in the psychological literature suggest that stressors associated with infertility and infertility treatments may contribute to dysfunctional parenting patterns and increased susceptibility to the *vulnerable child syndrome*. Parents who make the difficult choice to reduce a multifetal pregnancy either because of a fetal abnormality in 1 or more babies or to improve the chances for a healthier pregnancy outcome for the mother and the remaining baby or babies experience tremendous grief, anxiety, emotional distress, and guilt. Parents must cope with conflicting feelings of joy for their surviving infant or infants and sadness and grief associated with their remembrances of the babies who died. Recognizing that mothers and fathers often use different coping mechanisms that may influence their perceptions and responses is important. Golombok and Hahn have reviewed recent studies suggesting that ART does not seem to influence parenting and child development unduly. Two recent studies provide additional confirmation that successful ART does not predict mental health problems for adults as they transition to parenthood.

### ETHICAL AND LEGAL CONSIDERATIONS

Although new techniques offer multiple reproductive choices for couples and individuals, they also have created complex ethical and legal issues. For example, in ICSI, the male factor infertility that necessitated ICSI in the first place may be caused by a genetic defect, which the father may then pass unknowingly to his son. Another sensitive issue is that of sperm/gamete donation in which a single man may father many offspring. These offspring may then have multiple genetic half-siblings of whom they are not aware. If offspring become aware of this situation, this may pose quite an emotional burden. Therefore, some

advocate for limiting the number of gamete donations a man can make. Furthermore, there is the issue of preserving the anonymity of the donor and balancing that with the right of the offspring to realize their paternity.

Another controversial matter is that of egg freezing. This may be a chosen route for women who want to delay childbearing in order to pursue personal or career goals. As fertility is known to decline with age, freezing one's eggs at an earlier reproductive age may increase one's chance of future pregnancy. There is abundant information about this in the lay press, but a paucity of medical scientific data exists. When an egg is fertilized, it becomes an embryo. Controversy exists when clinics freeze embryos for later use. For example, what happens if embryo use never takes place? If the parents divorce or die, who gets custody of the embryos? In the United States, clinics request that parents specify how they want unused embryos handled. Some parents will donate them to other infertile couples or to scientists for research; others have them destroyed for fear of creating offspring they will never know. However, many individuals and religious institutions consider these embryos to be human beings and their disposal equivalent to murder.

In the United States, 100 women who are 50 years and older have borne children. Some ethicists think that this circumstance is not fair to the child, and, in the words of Fr. John Paris, Professor of Bioethics, "We're designing orphans by choice." For this reason, few fertility clinics in the United States will treat women older than 49 years. The ethics committee of the ASRM has issued guidelines stating, "Infertility should remain the natural characteristic of menopause." However, these guidelines are voluntary, and no law prevents physicians from treating any woman who requests it. Assisted reproduction is among the least regulated medical specialties in the United States with regard to the number of embryos transferred and age at which donor egg use is considered appropriate, among others.

Unfortunately, IVF is not covered by national health insurance in most of the world. According to the National Conference of State Legislatures, 15 US states have laws that require insurers to cover infertility diagnosis and treatment, with 8 states mandating IVF coverage. Although several European countries have ART covered by national health plans, most of the world does not. In the United States, because each attempt costs \$8,000 to \$10,000, patients often risk multiple births to avoid having to pay for a second visit. In most of the United States, high-quality assisted reproductive care is available mostly to people who have the financial means. The high cost of infertility treatment, especially advanced ART such as IVF, has resulted in reluctance on the part of most insurance companies to provide benefits for infertility and therefore has rendered such medical intervention financially inaccessible to a large portion of the infertile population. For many women then, OI is the primary method feasible to achieve pregnancy, despite the risk of

ovulation hyperstimulation and consequent multiple gestation.

## CONCLUSION

ART has allowed many couples who were once considered barren or beyond childbearing age to now experience the birth of a child. Furthermore, same-sex couples and single mothers or single fathers now have the option of procreating using their own genetic material through assisted reproduction, often involving surrogacy. Unfortunately, technological advances often come with uncertain and often imperfect outcomes; in the case of ART, these would include multiple births, prematurity, and low birth weight. Nonetheless, evidence-based medicine points to an overwhelmingly positive result of the advances in reproductive medicine, provided physicians are responsible and follow reasonable voluntary guidelines. Primary care physicians can be instrumental in guiding families through the information-gathering and decision-making process that is necessary when faced with the obstacle of infertility.

## Chapter 82

# PRENATAL DIAGNOSIS

Garfield Clunie, MD

Fifty percent of early pregnancy losses and 6% to 11% of stillbirths and neonatal deaths are attributed to chromosomal abnormalities. Nonlethal abnormalities can cause significant morbidity and occur in 0.7% of newborns. Although detecting all abnormalities may not be possible prenatally, some screening and diagnostic tests are available.

## GENETIC SCREENING: SERUM TESTING AND FIRST-TRIMESTER ULTRASOUND

Prenatal screening first became available more than 30 years ago and has been evolving ever since. Initially, maternal age and history were the only means of screening available. This practice changed in the mid 1980s when Cuckle demonstrated that combining maternal age with maternal serum alpha-fetoprotein (AFP) increased the detection rate for aneuploidy substantially. This maternal serum screening evolved into what is known as the *quadruple screen* typically performed at 15 to 18 weeks' gestation. Four serum markers (maternal serum AFP, human chorionic gonadotropin [hCG], estriol, and inhibin) are measured, yielding a 75% detection rate and a 5% false-positive rate.

In the early 1990s, Nicolaides reported an association between thickened nuchal translucency (NT) and aneuploidy. NT is a sonographic finding examining the subcutaneous tissue at the back of the fetal neck. NT represents a collection of fluid that appears as an echolucent line. Combining NT with maternal age can provide early detection of these pregnancies in women at higher risk for aneuploidy, with an 80% detection rate.

In 1996, Wald et al found 2 first-trimester serum markers—pregnancy-associated plasma protein A (PAPP-A) and free  $\beta$ -hCG—that stood out as markers for Down syndrome-affected pregnancies. PAPP-A values were found to be low, and free  $\beta$ -hCG values high in affected pregnancies. Using both analytes in combination with age provided a 62% detection rate at an earlier gestational age.

The combination of measuring NT and testing for serum markers is more effective than either of these measurements alone. At 11 weeks' gestation, the detection rate for Down syndrome is 70% using NT alone. This rate increases to 87% when PAPP-A and free  $\beta$ -hCG are added. A fully integrated model of screening in which serum metabolites from the second trimester are measured and the risk is not completely calculated until after this second trimester screen yields the best detection rate, at 96%. The major disadvantage is that the patient is not made aware of the first-trimester results, which not only removes the option of chorionic villus sampling (CVS) for early diagnosis, but also affects management options for

the patient if the decision is made not to continue the pregnancy. Stepwise sequential testing allows for calculation of risk after the first trimester. If the screening is negative, the patient would then undergo the quadruple screen, with a new risk calculated. If the first-trimester screen is positive, then the patient can have CVS for further assessment if so desired. Even with the positive screen, the patient can choose to forego CVS, and the physician should obtain the quadruple screen with a new risk calculated. The patient can then undergo amniocentesis for further determination. The detection rate for the stepwise sequential testing is 95%.

Most recently, maternal plasma tests for cell-free fetal DNA have been clinically validated as screening tests in high-risk populations. Large studies have demonstrated a detection rate of greater than 98% for Down syndrome. Presently, maternal plasma fetal DNA sequencing is best used as a secondary test after positive prenatal screening to determine which patients would benefit from invasive testing. Palomaki's study indicates that a positive result on the maternal plasma fetal DNA test increases the risk from the primary screen 490-fold, whereas a negative result reduces the risk of the primary screen 72-fold. As such, virtually all patients with a positive screen will be carrying a Down syndrome fetus and should be offered confirmatory invasive testing. Conversely, virtually all patients with a negative screen will have an unaffected fetus and they can avoid an invasive procedure. This approach minimizes the risk of procedure-related pregnancy loss of an unaffected fetus. While studies continue to confirm high sensitivity and specificity of maternal plasma DNA sequencing in detecting trisomies 21, 18, and 13 as well as monosomy X, it is important to note that (1) it remains a screening test and all positive results should be confirmed by amniocentesis or CVS; (2) currently, its efficacy is limited to the detection of the aforementioned aneuploidies; (3) as such, for women who are at increased risk of a child with a prenatally diagnosable disorder with Mendelian pattern of inheritance, microdeletion syndrome, and some other conditions, amniocentesis or CVS would still be indicated; and (4) the test has only been evaluated in high-risk populations. Studies demonstrating comparable performance of the test among low-risk populations are needed before it can be used as a primary screening approach.

### Genetic Diseases Specific to Ancestry

Carrier screening for specific genetic diseases is often determined by the individual's ancestry. For example, certain autosomal-recessive diseases are more prevalent in the Ashkenazi Jewish population. These diseases include Tay-Sachs disease, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia, Niemann-Pick disease, mucopolysaccharidosis type IV, Bloom syndrome, and Gaucher disease. Many of these conditions are lethal in childhood and are associated with significant morbidity. As another example, some hematologic disorders are more prevalent in some populations than in others (eg, sickle cell disease in blacks,  $\alpha$ -thalassemia in Southeast Asians,  $\beta$ -thalassemia in patients from Mediterranean countries).

Carrier screening should be offered to couples either preconceptionally or in early pregnancy so that prenatal diagnostic testing is an option for the couple.

### Invasive Testing

Invasive testing should be offered to women of advanced maternal age or with positive first- or second-trimester screening for aneuploidy. It should also be offered to couples at risk for a specific genetic disease. Options for invasive testing include 1 of 2 ultrasound-guided procedures, CVS performed between 10 and 13<sup>7</sup>/<sub>7</sub> weeks' gestation, and amniocentesis done from 15 weeks' gestation onward. CVS is performed by inserting a needle into placental tissue and extracting villi. An amniocentesis is performed by inserting a needle into the amniotic sac and withdrawing amniotic fluid. In experienced hands, the procedure-related loss rate for CVS is approximately 0.5% to 1%. Traditionally the procedure-related loss rate was similar to that of amniocentesis, but newer literature has shown that the loss rate with amniocentesis may be as low as 1 per 1,000. Studies are underway to assess for loss rates with CVS as a direct comparison with amniocentesis.

In addition, the American College of Obstetricians and Gynecologists has published new guidelines for women who have a prenatal ultrasound in which a major fetal anomaly is found. Regardless of maternal age, chromosomal microarray analysis should be performed in addition to routine karyotype analysis.

## SECOND- AND THIRD-TRIMESTER ULTRASOUND

Ultrasound has been the best method for imaging the fetus since the 1950s. With the advent of real-time sonography, higher-frequency transducers, and Doppler sonography, the ability to provide accurate prenatal diagnoses has greatly improved. Most pregnant women in the United States will undergo an ultrasound examination, although the role of routine ultrasound has been a focus of controversy. The American College of Obstetricians and Gynecologists has specific recommendations for the role of ultrasound in each trimester of pregnancy. The focus of this chapter is on the diagnosis and evaluation of major fetal anomalies.

### Central Nervous System

#### Neural Tube Defects

Neural tube defects (NTDs) are congenital structural abnormalities of the brain and vertebral column. These abnormalities can occur as an isolated event, with other malformations, or as part of a genetic syndrome. With an incidence of 1 to 2 per 1,000 live births (LBs) worldwide, NTDs are the second most common major congenital anomaly.

NTD prevalence rates vary geographically and by ethnicity. Isolated NTD is multifactorial in origin; there are contributing genetic and environmental factors that increase risk. Periconceptional dietary supplementation with folic acid significantly reduces the risk of NTDs. In the United States, where folic acid fortification of flour and grain-based cereals is common and women are encouraged to take folate-containing vitamins before becoming pregnant, the prevalence

rate for all NTDs (anencephaly, spina bifida and encephalocele) is 6.38 per 10,000 LBs, adjusted for maternal race and ethnicity. The spina bifida rate is 3.50 per 10,000 LBs (1 in 2,858 births). Hispanic women have the highest risk of having a child with spina bifida in comparison with non-Hispanic black and non-Hispanic white women. Recent data reveal that a declining number of women, particularly minority women, are consuming folic acid supplements before pregnancy.

Embryologically, the neural plate appears during the third week of gestation and gives rise to neural folds that fuse in the midline to form the neural tube. Closure of the neural tube is usually complete by the end of the sixth gestational week. Failure of this process leads to the defect. The cause is a result of genetic, environmental, and dietary influences. Folic acid plays an important role in the proper formation of the neural tube, which is mediated via the enzyme methylenetetrahydrofolate reductase (MTHFR). Deficiency in folic acid has been implicated in part of the mechanism for the formation of NTDs. Such is the case not only in terms of dietary deficiency, but also as a result of the mechanism of teratogenic effects of certain medications, such as antiepileptic drugs. Supplementation with folic acid has been shown to decrease the incidence and recurrence.

NTDs can be separated into 2 categories: cranial and spinal. Cranial defects include anencephaly, exencephaly, encephalocele, and iniencephaly. These defects occur in the skull, scalp, and brain tissue and result in death. Defects in the caudal region are more commonly known as spina bifida. These defects are malformations of the spinal cord, meninges, and vertebrae and are compatible with life. Caudal-region defects that are confined to the spine are further differentiated as open (neural tissue exposed), usually involving the spine or cranium, or closed (neural tissue not exposed).

Maternal serum screening is routinely offered to all pregnant women. AFP is the maternal serum marker that is used as a screening tool for open NTDs. AFP is measured at 15 to 20 weeks and is expressed as multiples of the median (MOM). A value above 2.0 to 2.5 MOM is considered abnormal and necessitates further evaluation, such as a repeat test, ultrasound examination, and possibly amniocentesis. Other factors can affect interpretation, such as knowledge of proper gestational age, maternal weight, multiple gestations, and the presence of other anomalies.

Ultrasound is effective for detecting NTDs as well. In experienced hands, ultrasound can be 97% sensitive and 100% specific, negating the need for maternal serum AFP. NTDs can be identified on ultrasound by the presence of irregularities of the bony spine or a bulging of the contour of the fetal back. The posterior fossa of the fetal brain may also provide clues that an NTD is present. The *banana sign* refers to the shape the cerebellum makes as a result of the herniation of the spinal tissue and is one such clue. Spinal herniation also produces the *lemon sign*, which refers to flattening of the frontal contour of the fetal calvarium. Ventriculomegaly may also be seen. At the time of diagnosis, an amniocentesis should be offered. This test can provide information regarding the karyotype,

particularly if other anomalies are detected; it also serves as a confirmatory test. AFP levels will be increased in amniotic fluid, which can also be tested for acetylcholinesterase (AChE). AChE is an enzyme found in blood cells, muscle tissue, and nerve tissue. An increase in AChE levels suggests an open NTD with 96% accuracy.

Prognosis depends on the type and location of the lesion. As stated previously, lesions involving the brain and skull are lethal; those involving the spine are usually compatible with life. An important point to note is the existence of indications regarding ambulatory, urologic, and bowel function, which is important when counseling parents regarding further interventions or when counseling parents considering termination of the pregnancy. In utero intervention is available for this anomaly (see Chapter 83, Fetal Interventions). The recently published multicenter, randomized MOMS trial (Management of Meningomyelocele Study) demonstrated that fetal intervention may alter the natural history of meningocele. Eligible fetuses randomized to undergo fetal repair between 19 and 26 weeks' gestation experienced lower mortality and morbidity in comparison with fetuses who underwent standard postnatal repair. However, risks to the mother and fetus undergoing prenatal repair were significant. Longitudinal follow-up of these 2 groups of children is ongoing and will provide additional insights into the risks and benefits of prenatal intervention.

### Ventriculomegaly and Hydrocephalus

Ventriculomegaly is defined as an increased diameter of the fetal lateral ventricles of more than 10 mm. Hydrocephalus is defined as a pathologic increase in intracranial cerebrospinal fluid (CSF). These terms are often used interchangeably in prenatal diagnosis, though technically hydrocephalus refers to intracranial pressure, which cannot be measured in the prenatal setting.

CSF is produced within the ventricular system, with one-half from the choroid plexus and the other half from the cerebral capillaries. Circulation is unidirectional and moves from the lateral ventricles through the foramen of Monroe to the third ventricle. It then travels to the fourth ventricle after passing through the aqueduct of Sylvius and ends up in the spinal subarachnoid space or basal cisterns. It is then reabsorbed in the venous sinuses. In the event of either production of CSF that exceeds absorption or mechanical obstruction of flow, ventriculomegaly can result. Ventriculomegaly can be an isolated finding, with an incidence of 1.4 to 20 per 1,000 LBs, or it may be an indicator of other underlying central nervous system (CNS) anomalies (eg, aqueductal stenosis) or associated extra-CNS anomalies (eg, NTDs).

The lateral ventricles can be readily assessed with ultrasound. The atria of the lateral ventricles measure, on average, 7 mm; the upper limit of normal is 10 mm. Once the diagnosis has been made, a thorough ultrasound examination should permit the operator to assess for any other associated anomalies. Amniocentesis for karyotyping should be offered, because a 4% to 14% association has been reported with aneuploidy,

which may also provide additional information if an NTD is suspected. Family history should be carefully reviewed because of the association with some X-linked conditions. Limitations of ultrasound evaluation exist, particularly for cortical malformations. For this reason, fetal magnetic resonance imaging (MRI) is recommended when a CNS anomaly is diagnosed, as it may provide additional information that alters diagnosis and management in up to 40% of cases.

Prognosis depends on the presence of other anomalies. In patients continuing the pregnancy, surveillance of the ventriculomegaly is performed with serial ultrasounds. Although in utero treatment has been attempted, no improvement in outcome has resulted. Most fetuses will have normal head circumference; therefore, cesarean section should be considered only for routine obstetric reasons.

### **Choroid Plexus Cysts**

Choroid plexus cysts (CPCs) are thought to be neuroepithelial folds that fill with CSF and cellular debris. A CPC is a common ultrasound finding in healthy fetuses in the second trimester and has an incidence of 0.2% to 3.6%. The choroid plexus is a major source of CSF. Development begins at 6 to 7 weeks' gestation. They grow rapidly, filling 75% of the lateral ventricles by 9 weeks' gestation and reaching full size by 20 weeks' gestation.

The typical appearance on ultrasound is a sonolucent structure with well-defined borders. CPCs are generally small. When determining the actual risk for trisomy 18 with isolated CPCs, the physician must take into consideration maternal age and adjust it according to the maternal serum screen risk, if available. The risk does not depend on the age at diagnosis, but rather on the size or laterality of the cysts.

Once CPCs are noted on ultrasound, a detailed ultrasound should be performed to determine the presence of other anomalies, particularly those associated with trisomy 18 (ie, congenital heart defects, rocker-bottom feet). In up to 75% of fetuses with trisomy 18, additional abnormalities will be detected. Once the risk of aneuploidy is determined, amniocentesis can be offered. Many physicians suggest invasive testing only in the setting of other anomalies or if the mother is older than 35 years. In the setting of an isolated CPC, the prognosis is good, and most CPCs will resolve by the third trimester; those that do persist are usually benign. However, resolution does not change the small risk of aneuploidy.

### **Craniofacial Defects**

The orofacial cleft is the most common craniofacial malformation found in the newborn. Clefting can be of the lip or palate in isolation or together. Of all cases, 60% to 75% will involve the lip with or without the palate, and 25% to 40% will involve the palate alone. Up to 80% of cases are unilateral; left-side involvement is twice as common as right-side involvement. The overall incidence is population dependent. In the white population, incidence is 1 per 1,000 LBs; in the black population, incidence is 1 per 2,273 LBs. The incidence among Asians is higher, with reported rates of 1 per 500 LBs.

Craniofacial development involves migration, proliferation, and differentiation of facial mesenchyme

derived from neural crest cells. Many genes are involved in the regulation of this process. Normally, fusion of 3 mesodermal processes occurs, which is complete by 7 weeks' gestation. Failure of this process leads to clefting involving the lip, whether it is in isolation or involves the palate. Cleft palate in isolation is different; although fusion must also take place, the formation of a cleft palate also involves other processes, particularly proper movement of palatal shelves and the tongue.

The cause is genetic, as well as environmental. The genes involved, *Dlx* and *sonic hedgehog*, influence cell programming and cell differentiation. Environmental factors are the result of teratogenic effects. Medications, including antiepileptic drugs and steroids, have been implicated. Cigarette smoking, alcohol consumption, and folic acid deficiency have also been found to have an association.

Orofacial clefting can be detected on ultrasound, but only after 14 weeks, because this is the time that the fetal face assumes its normal form. Isolated cleft palate can be extremely difficult to diagnose prenatally. Once detected, a thorough ultrasound examination should be performed to assess for other anomalies, particularly of the CNS and cardiac systems. If another anomaly is detected, then chromosomal abnormalities can be seen in as many as 60% of these fetuses. Cleft lip or palate in isolation is not associated with aneuploidy. However, amniocentesis can be offered, and it may be helpful in finding other anomalies.

No prenatal interventions are available. Management of the pregnancy should otherwise be routine. Parents should meet with the craniofacial surgeons to discuss the steps involved in postnatal surgical management.

### **Neck**

#### **Cystic Hygroma**

Cystic hygroma is a lymphatic malformation or lymphangioma located at the level of the neck. Lymphatic fluid collects in the jugular system because of a blockage to flow. The overall prevalence in the first trimester is 1 per 100 LBs.

Cystic hygromas can be large, single or multiloculated, fluid-filled cavities. They are easily identifiable on ultrasound examination in the first trimester. Cystic hygromas tend to be largest in the nuchal region but can extend the full length of the fetus. Once a cystic hygroma is detected, a thorough ultrasound examination should be performed. The skull and spine should be examined to differentiate cystic hygroma from an NTD. The physician should thoroughly assess for other signs consistent with hydrops fetalis (skin edema, ascites, pericardial or pleural effusions). A 50% chance of aneuploidy exists when diagnosis is made in the first trimester. The most common aneuploidy is Down syndrome (trisomy 21), but it can also be seen with trisomy 13 and 18, as well as Turner syndrome (45,X). Therefore, invasive testing such as CVS or amniocentesis should be performed. A fetal echocardiogram should also be performed to determine the presence of any cardiac defects. No fetal intervention is available. Serial sonograms should be performed to assess for polyhydramnios resulting from

fetal inability to swallow, which can lead to uterine irritability and even preterm labor.

This finding is associated with significant mortality because of the high incidence of coexisting chromosomal abnormalities and other malformations. In the small group of fetuses in which this disorder is found in isolation with normal karyotype, the prognosis can be excellent. The major concern in this group is the ability to maintain the airway at the time of delivery, which may require an ex utero intrapartum treatment (EXIT) procedure, during which uteroplacental blood flow and gas exchange are maintained while the fetal malformation is surgically treated (see Chapter 83, Fetal Interventions).

### Goiter

Fetal goiter, also known as thyromegaly, is an enlargement of the fetal thyroid gland. It can occur in the maternal hyperthyroid, euthyroid, or, most commonly, hypothyroid state. When fetal goiter occurs in the hypothyroid state, it may result from transplacental passage of antithyroid medication, antithyroid antibodies, iodine deficiency, or congenital thyroid metabolic disorders. A fetal goiter that occurs in the hyperthyroid state is most commonly caused by transplacental passage of thyroid-stimulating antibodies, as in maternal Graves disease. Overall, this finding is rare. The fetal thyroid becomes fully responsive to thyroid-stimulating substances only in the second trimester; therefore, diagnosis before 20 weeks is unlikely.

A fetal goiter can be seen on ultrasound examination as a homogenous anterior neck mass. In severe cases, the neck is in a persistent state of hyperextension. Polyhydramnios may also occur as a result of fetal impairment of swallowing. Other abnormal ultrasound findings include fetal tachycardia, intrauterine growth restriction (IUGR), and hydrops. Signs of fetal hypothyroidism include cardiomegaly and fetal heart block. Even with these findings, accurately predicting fetal status may be difficult.

Given the difficulty in accurately determining fetal status with ultrasound alone, periumbilical cord blood sampling should be considered to evaluate thyroid hormone levels in fetal serum. The fetus can then be treated through administration of the proper medication to the mother. If the mother is euthyroid, then she may need supplementation to maintain her thyroid function. In addition, the fetus should be monitored with serial ultrasounds to assess amniotic fluid, signs of hydrops, and growth.

At delivery, the neonatal professionals skilled in neonatal resuscitation should be present and aware of the diagnosis and the therapy that has been instituted. The fetal airway must be maintained; thus an EXIT procedure including tracheostomy or bronchoscopy may be necessary. In such instances, a pediatric otorhinolaryngologist or pediatric surgeon will need to be present at the delivery to secure the newborn's airway.

## Thoracic Defects

### Bronchopulmonary Sequestration

Bronchopulmonary sequestration (BPS) is a rare congenital malformation of the lower respiratory tract. It

is made up of a cystic mass of nonfunctional pulmonary tissue. No communication occurs with the normal bronchopulmonary tree, and it derives its blood supply from anomalous vessels. BPS is thought to comprise 0.1% to 6% of all congenital pulmonary lesions (see Chapter 100, Respiratory Distress and Breathing Disorders of the Newborn).

BPS is believed to originate from a supernumerary lung bud that develops caudally to the normal lung buds and then migrates with the esophagus. Two forms have been described: intralobar and extralobar. Intralobar is more common (75%) than extralobar; it is located in the lobe and lacks its own visceral pleura. Extralobar is seen in the rest of the cases; it is located outside the normal lung and has its own visceral pleura. Extralobar lesions can be intrathoracic or subdiaphragmatic.

On ultrasound examination, BPS is a solid echogenic mass characterized by its location, vascular supply, and association with other abnormalities. Most lesions are located in the lower lobes, but they can be anywhere in the thorax or can be subdiaphragmatic. They have their own blood supply, which tends to arise from the thoracic aorta. Demonstration of the aberrant blood supply by Doppler sonography usually confirms the diagnosis. Other sonographic findings may be pleural effusion, mediastinal shift, and hydrops. Cardiac and vertebral anomalies may also be present. Amniocentesis should be offered if other anomalies are present. A fetal echocardiogram should be performed because of the disorder's association with cardiac anomalies.

The natural history of BPS tends to be variable. Some lesions regress; others can lead to hydrops, usually from vascular compression. The prognosis depends on the other associated findings. Cases complicated by hydrops can be fatal. Survival rates for fetuses with pleural effusion or polyhydramnios have been reported as 22% and 30%, respectively. Because of this, for fetuses that develop hydrops before 30 weeks' gestation, intervention can be considered via shunting. In cases where hydrops develops after 30 weeks' gestation, early delivery should be considered.

### Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM), formerly known as congenital cystic adenomatoid malformation (CCAM), is a rare lesion of the lower respiratory tract. It is composed of multicystic masses of pulmonary tissue, is unilobar in 80% to 95% of cases, and can affect any lobe of the lung. The incidence has been reported as being 1 per 10,000 to 1 per 35,000 LBs.

CPAM arises from an abnormality in branching and maturation of bronchiolar structures, which begins around 5 to 6 weeks' gestation. Three types of CPAMs have been identified and are thought to originate at different levels of the respiratory tract at different times during development. Type I is the most common and accounts for 50% of these lesions. Lesions are characterized by either single or multiple large cysts (3–10 cm). The cysts are lined by ciliated pseudostratified columnar epithelium; these lesions are thought to be distal in origin because they have well-differentiated

tissue. Type II is the second-most common type and accounts for 40% of CPAM cases. These lesions are made up of smaller cysts (<1 cm) lined with ciliated cuboidal or columnar epithelium. This type of malformation has a high association (60%) with other anomalies, including genitourinary, cardiac, and skeletal anomalies, because the disorder likely occurs earlier in development. Type III is the least common (10%). It is characterized by large homogeneous microcystic masses (<0.5 cm). A mixture of solid and cystic tissue is found from adenomatoid proliferation of the distal airways and spaces. Lesions tend to be large and lack differentiation. This insult is thought to occur between 26 and 28 days' gestation.

CPAMs have been divided into 5 different types based on histologic characteristics (type 0 through type IV). Thus to confirm the type, postnatal histology is needed. Adzick et al proposed a modification to Stocker's classification of CPAMs based on anatomy and sonographic appearance to assist in predicting prenatal outcome. Macrocytic CPAMs have single or multiple cysts larger than 5 mm in diameter and microcystic CPAMs have cysts that are smaller than 5 mm in diameter, giving them a more homogeneous appearance. Microcystic lesions increase the risk of development of hydrops. Because they can be quite large, microcystic lesions can also cause mediastinal shift, pulmonary hypoplasia, and polyhydramnios.

A detailed Doppler ultrasound examination should be performed to differentiate these lesions from others, such as congenital diaphragmatic hernia (CDH) or BPS, as well as to assess for other associated anomalies, particularly if a type II lesion is suspected. A fetal echocardiogram should be performed to rule out cardiac anomalies, particularly in the setting of hydrops. Fetal karyotyping should be offered in the setting of other anomalies or hydrops. Isolated CPAM has a less than 1% association with aneuploidy; however, karyotyping still should be performed if plans are in place for in utero intervention, because an abnormal result may affect the decision to do so. Serial sonography should be performed to look for signs of hydrops. These lesions can occasionally regress.

Prognosis for these lesions depends on the type of CPAM present. Fetuses with type I tend to do well; fetuses with type III disorder have a poorer prognosis. The prognosis for type II depends on the severity of other lesions, if present. In utero treatment with decompression and possible shunt placement may be reasonable when hydrops is present before 32 weeks' gestation. An EXIT procedure should be considered at the time of delivery if there is concern for the airway.

### **Congenital Diaphragmatic Hernia**

Congenital diaphragmatic hernia occurs when a defect develops in the diaphragm that allows the abdominal viscera to herniate into the fetal thorax. Most CDHs are unilateral (98%), with the left side being the most common. The incidence is 1 per 2,200 LBs.

The defect occurs either as failure of closure of the pleuroperitoneal folds or as a defect in migration of muscle fibers during the development of the diaphragm at 9 to 10 weeks' gestation. When the defect is present, it allows herniation to occur. Because this

defect happens so early in lung development, the number of bronchial branches becomes reduced, leading to pulmonary hypoplasia. These changes are more pronounced on the side of the herniation, but the contralateral lung can be affected by compression of a shifted mediastinum.

On ultrasound examination, one of the key clues to diagnosing CDH is the location of the stomach bubble. When viewing the fetal chest, the stomach bubble is seen in the same plane as the heart in cases of CDH. Peristalsis of the bowel in the thorax may also be noted. Determination of potential liver herniation is important for prognosis and the possibility for intervention. MRI may be suitable for this purpose. Fifty percent of CDHs are associated with other anomalies, including cardiac, genitourinary, and gastrointestinal anomalies. A fetal echocardiogram should be performed to assess for cardiac defects. Chromosomal abnormalities can be seen in 10% to 20% of cases; therefore, amniocentesis should be offered, particularly if in utero intervention is being considered.

Prognosis depends on such factors as karyotype, presence of liver herniation, associated anomalies, and ratio of lung area to head circumference. This ratio estimates the contralateral lung size and mediastinal shift at the level of the atria. Originally thought to predict survival, this ratio is more useful in assessing morbidity than mortality. Up to 30% of these fetuses can be stillborn; therefore, close surveillance in the third trimester is warranted. Serial ultrasounds may also be performed to assess growth and amniotic fluid volume. In utero intervention may play a role (see Chapter 83, Fetal Interventions). Delivery should be at an appropriate tertiary care center.

### **Cardiovascular Defects**

Cardiac anomalies are the most common congenital lesion, with an incidence of 5 to 8 per 1,000 LBs. Thus, review of cardiac anatomy is an integral part of the basic fetal anatomic survey and is ideally preformed between 18 and 22 weeks' gestation. Most cardiac lesions are detected in low-risk populations; however, several risk factors call for more detailed evaluation, such as a fetal echocardiogram. These risk factors can be divided into 3 general categories: familial, maternal, and fetal. Familial risk factors include parental congenital heart disease, a previous affected child, or a family history of a syndrome associated with heart disease (eg, Noonan syndrome). Maternal risks include diabetes, lupus, teratogen exposure (eg, lithium), and infection (eg, rubella). Fetal risks include detection of another anomaly, suspicion of aneuploidy, arrhythmia, and evidence of hydrops. A strong association exists between cardiac anomalies and aneuploidy; therefore, amniocentesis should be offered if a cardiac anomaly is discovered. Patients should meet with pediatric cardiologists or a pediatric cardiothoracic surgeon (or both) to discuss prognosis and postnatal treatment, including surgery. The following section will provide a brief review of some of the most common cardiac anomalies.

#### **Atrioventricular Canal Defect**

Atrioventricular (AV) canal defects consist of atrial septal defect (ASD) and ventricular septal defect (VSD)

and a single common AV valve. They are also known as endocardial cushion defects. AV canal defects account for 1% to 5% of all cases of congenital heart disease.

On ultrasound examination, a large defect is noted when looking at the 4-chamber view of the heart, representing the defects in the inferior portion of the atrial septum and the superior portion of the ventricular septum. The normal conduction of the heart is affected by the large defect, often leading to bradyarrhythmia. Additional cardiac malformations may be present, including tetralogy of Fallot, coarctation, and pulmonary stenosis. The prognosis depends on the presence of other associated anomalies, including hydrops and aneuploidy.

### **Truncus Arteriosus**

Truncus arteriosus occurs when a single, large ventricular outflow tract arises from both the left and right ventricles. It is rare, accounting for only 1.5% of heart defects, with an incidence estimated at 3 per 100,000 LBs. Four subtypes were originally described. Type I has a single pulmonary trunk that divides into right and left pulmonary arteries. Type II has 2 pulmonary arteries arising from the posterior of the truncus. Type III has 2 pulmonary arteries from the lateral aspects of the truncus. In type IV, the pulmonary arteries are absent, but collaterals arise from the descending aorta.

When visualizing the outflow tracts using ultrasound, a single, large ventricular outflow tract is seen. The right-ventricular outflow tract is not seen. Abnormalities of the aortic arch may also be seen, as well as the presence of hydrops.

### **Hypoplastic Left and Right Ventricles**

Hypoplastic left ventricle, also known as hypoplastic left heart syndrome, occurs when hypoplasia of the left ventricle, atresia of the aortic and mitral valves, and hypoplasia of the aortic arch are present. Each of these components can occur at varying degrees. Hypoplastic left heart syndrome accounts for 9% of all congenital heart defects, with an incidence of 1 per 10,000 LBs.

Hypoplastic right heart syndrome, also known as pulmonary atresia with intact ventricular septum, occurs when hypoplasia of the right ventricle, pulmonary atresia, and occasionally tricuspid atresia are present. This lesion accounts for less than 3% of congenital heart defects, with an incidence of 1 per 144,000 LBs.

Both lesions are usually easy to detect on ultrasound examination. When looking at the 4-chamber view of the heart, an inequality of the ventricles can be seen. The affected side will appear as a small remnant and will seem hypocontractile. Both lesions may not be as clear on second-trimester ultrasound but will evolve over time. Careful anatomic survey should be performed to assess for other cardiac and extracardiac anomalies.

### **Tetralogy of Fallot**

Tetralogy of Fallot is a malformation that consists of VSD, right-ventricular outflow obstruction, the aorta

overriding the ventricular septum, and right-ventricular hypertrophy. Tetralogy of Fallot is thought to occur as a result of misalignment during embryogenesis. It accounts for 5% to 10% of congenital heart defects and has an incidence of 2 per 10,000 LBs.

On ultrasound examination, an overriding aorta is the key feature for diagnosis. Color Doppler sonography may be helpful in detecting the VSD. Detailed sonography should be performed to assess for extracardiac malformations.

### **Transposition of the Great Vessels**

In transposition of the great vessels, the aorta connects with the right ventricle, and the pulmonary artery connects with the left ventricle. Two types have been identified: complete and corrected. Complete transposition of the great vessels, also known as D-transposition, is the more common of the 2 forms. In this form, the aorta comes off the right ventricle, and the pulmonary artery comes off the left ventricle. ASD and VSD defects are also commonly seen. It usually causes no hemodynamic compromise in utero. The corrected type of transposition of the great vessels, also known as L-transposition, refers to a connection of the right atrium to the morphologic left ventricle that connects to the pulmonary artery, whereas the left atrium connects to the morphologic right ventricle and then to the aorta. It is an abnormality in conotruncal development at 4 to 5 weeks' gestation and accounts for 4% to 6% of congenital heart defects.

The diagnosis is made on ultrasound examination when the aorta is identified as originating from the right ventricle. Demonstrating the vessels supplying the head and neck helps identify the aorta. The normal crossing over of the pulmonary artery and aorta is not seen. The outflow tracts seem to run in parallel, which is of importance, particularly in L-transposition, which can be difficult to diagnose. A detailed ultrasound examination should be performed to assess for other cardiac anomalies, such as pulmonic stenosis and coarctation, as well as extracardiac anomalies.

### **Atrial and Ventricular Septal Defects**

ASD is a malformation in the development of the interatrial septum. Three different types are possible, depending on location. An inlet ASD is located near the entrance of the superior vena cava. A primum or outlet ASD is located in the body of the septum. Secundum ASDs occur because of an absence of the foramen ovale flap. These lesions are usually of no concern in utero because of normal right-to-left shunting. ASDs comprise 7.5% of all congenital heart defects.

A VSD is a malformation in the development of the interventricular septum. It is the most common congenital heart defect. VSDs can occur in the muscular or membranous portions of the septum. Muscular VSDs are bordered on all sides by muscle and may be further categorized as inlet, trabecular, or infundibular. Subvalvular VSDs, which are directly related to the AV and semilunar valves, may also occur.

Prenatal diagnosis of ASD is difficult because of the normal presence of the foramen ovale. VSDs can also be problematic, particularly if the lesion is small. Color Doppler sonography may be useful in demonstrating

flow across the septum. A detailed ultrasound examination should be performed to assess cardiac anatomy further. Serial ultrasounds should be performed to assess growth and to monitor for signs of fetal hydrops.

### **Arrhythmias**

The normal fetal heart rate ranges from 120 to 160 beats per minute (bpm). In bradycardia, the rate is sustained below 120 bpm; in tachycardia, the sustained rate exceeds 160 bpm. Bradyarrhythmias are caused by congenital heart block and are most commonly associated with structural anomalies such as transposition and AV canal defects. Bradyarrhythmia can also be found in a structurally normal heart when transplacental passage of certain maternal antibodies occurs in mothers with connective tissue disorders (ie, anti-Ro and anti-La antibodies in patients with systemic lupus erythematosus). First-, second-, or third-degree heart block can exist, with the last of these 3 blocks being the most common. Echocardiography should be performed to assess for cardiac anomalies. Serial ultrasounds should be performed to assess fetal growth. Bradycardia is generally well tolerated, but can lead to hydrops in up to 25% of fetuses. If evidence exists of fetal compromise after 30 weeks' gestation, then delivery should be considered. Medical treatments have been proposed and are divided into those that suppress maternal immune response, such as corticosteroids, and those that increase fetal ventricular rate, such as  $\beta$ -mimetics.

Tachyarrhythmias are irregular cardiac rhythms caused by extrasystoles, supraventricular tachycardia, atrial flutter, or fibrillation. Extrasystoles may originate in the atria, AV node, or ventricles, and usually resolve spontaneously. The most common are supraventricular tachycardias, many of which are re-entry dysrhythmias. Atrial flutter is from a single re-entry circuit within the atria with varying degrees of block at the AV node. Atrial fibrillation is from multiple small intraatrial re-entry circuits, and organized atrial contraction is absent. These dysrhythmias have the potential for serious sequelae leading to hydrops. Complete cardiac survey should be performed to assess for cardiac anomalies. In utero treatment by administration of antiarrhythmics to the mother can convert the aberrant rhythm. Serial sonograms should be performed to assess fetal growth and to assess for signs of hydrops.

### **Abdominal Wall Defects**

#### **Gastroschisis**

Gastroschisis is a full-thickness defect of the abdominal wall that leads to evisceration of the abdominal contents. The defect is thought to be the result of vascular compromise of either the umbilical vein or the omphalomesenteric artery. It typically arises to the right of the umbilicus. The incidence is reported as 1 per 4,000 LBs.

Increased levels of AFP in maternal serum will be present with gastroschisis and other wall defects. Midgut herniation is normal up until 11 weeks' gestation. Herniation noted on ultrasound examination beyond this time is abnormal. Protruding bowel can be easily seen. Color Doppler sonography can be

used to demonstrate the insertion of the umbilical cord medial to the defect. A thorough ultrasound evaluation should be performed to assess for other anomalies. Gastroschisis is not associated with chromosomal abnormalities. Amniocentesis should be offered if other anomalies are detected. Serial sonograms are performed to monitor growth and bowel integrity.

The prognosis with gastroschisis is generally good. No fetal intervention is available. Mode of delivery is for obstetric indications. Parents should meet with a pediatric surgeon to discuss postnatal surgical treatment.

For more information, see Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn.

#### **Omphalocele**

An omphalocele is a defect of the medial abdominal wall characterized by the lack of abdominal muscles, fascia, and skin. Protrusion of the intra-abdominal contents occurs with a covering membrane that consists of peritoneum and amnion. In contrast to gastroschisis, the umbilical cord inserts into the membrane at its apex. Omphaloceles are categorized as either liver-containing or non-liver-containing.

During development, the embryo undergoes a series of cranial, caudal, and lateral folding events. When failure of lateral folding occurs at the third to fourth week of gestation, omphaloceles can occur. The incidence is 1 per 4,000 LBs. Maternal serum screening can be helpful making this diagnosis.

On ultrasound examination, bowel herniation can be noted. The membranous covering confirms the diagnosis of omphalocele. The presence or absence of liver herniation should be noted, because this finding is important for determining prognosis. Color Doppler sonography can demonstrate the umbilical cord entering the sac. Omphalocele is strongly associated with other anomalies and with chromosomal abnormalities. Therefore, a thorough ultrasound evaluation should be performed, as should amniocentesis. Serial sonograms should be performed to assess fetal growth.

The prognosis depends on finding other congenital anomalies and on chromosome evaluation. Mortality may be as high as 20% to 30%. Large lesions have limited potential for closure. Patients should meet with pediatric surgeons to discuss postnatal surgical treatment.

### **Gastrointestinal Defects**

#### **Duodenal Atresia**

Duodenal atresia is characterized by complete obliteration of the duodenal lumen. It is the most common type of congenital small-bowel atresia. The incidence is 1 per 10,000 LBs.

At 5 weeks' gestation, the lumen of the duodenum is obliterated by proliferating epithelium. Normally, recanalization occurs, and the lumen is restored by 11 weeks. Failure of the recanalization process results in duodenal atresia or stenosis. Three types are described. Type I is membranous mucosal atresia with an intact muscular wall. The proximal duodenum is

ballooned out, and the distal duodenum is narrowed. Type II duodenal atresia is rare. It has a short fibrous cord connecting the 2 ends of the duodenum. Type III has a complete separation between the duodenal ends and can be associated with gallbladder anomalies.

Most cases can be diagnosed by ultrasound but generally not until the third trimester. The duodenum is persistently dilated and the stomach is filled with fluid, leading to the classic *double-bubble* appearance. Significant polyhydramnios is usually present because of the fetal inability to swallow, which can lead to uterine irritability and preterm labor and may often be the reason why a mother presents for an ultrasound evaluation. Thirty percent of fetuses with duodenal atresia will have Down syndrome; therefore, amniocentesis should be performed. A thorough cardiac evaluation should be conducted, because an association exists with heart malformations.

The prognosis is related to associated malformations and karyotype. The risk of preterm labor and its associated morbidity and mortality is increased. Surgical repair is required early in life and in some cases can be performed with a minimally invasive approach.

### **Echogenic Bowel**

Echogenic bowel is a sonographic finding in which the bowel seems to have the same echogenicity as the surrounding bone. The incidence ranges from 0.4% to 1% in the second trimester. Echogenic bowel can be a normal variant. However, it has been associated with chromosomal abnormalities, fetal cystic fibrosis, cytomegalovirus infection, IUGR, intra-amniotic bleeding, and intestinal abnormalities. Once echogenic bowel is detected, an amniocentesis should be considered to enable testing for karyotype, cystic fibrosis, and infection studies. No fetal intervention is available. Prognosis depends on the cause.

## **Genitourinary Defects**

### **Ambiguous Genitalia**

Sexual differentiation does not occur until 6 to 7 weeks' gestation, even though genotype is determined at the time of conception. Before 6 to 7 weeks' gestation, the gonads are undifferentiated. The presence of particular hormones and the expression of specific genes aid in the differentiation process. Masculinization is induced by the activity of dihydrotestosterone, which is formed from testosterone. Absence of or insensitivity to this hormone leads to the formation of female genitalia. Disruption in this pathway can lead to ambiguous genitalia. The overall incidence is 1 per 5,000 LBs.

Abnormalities of sex differentiation are chromosomal, gonadal, or phenotypical. Three categories are described. The true hermaphrodite has both ovarian and testicular tissue present. Female pseudohermaphrodites are overmasculinized females. Male pseudohermaphrodites are undermasculinized males. Many methods have been described to determine sex on ultrasound examination. (See Chapter 243, Disorders of Sex Development.)

Amniocentesis should be performed to determine genotype. Testing for inborn errors of metabolism should be performed. A complete maternal history

and physical examination should be performed to assess for signs of androgen excess, hormone ingestion, or family history of similar findings.

### **Hydronephrosis**

Hydronephrosis is dilatation of the renal pelvises and calyces. It is among the most commonly reported ultrasound findings and comprises 75% of diagnosed renal abnormalities. The severity can range from mild to severe and depends on gestational age. Hydronephrosis may be physiologic or pathologic. Distinguishing the 2 entities requires thorough ultrasound evaluation and close follow-up. The incidence of mild hydronephrosis is reported as 1 per 100 LBs; for severe hydronephrosis, as in ureteropelvic junction obstruction, the incidence is 1 per 100,000 LBs. The finding may be unilateral or bilateral.

When visualizing the kidneys on ultrasound evaluation, the renal pelvises are dilated when measured. The absolute measurement depends on gestational age, because normal dilatation exists with advancing gestational age. A thorough ultrasound evaluation should be performed to assess for any other abnormalities. Amniocentesis should be offered because of the increased risk of aneuploidy in severe cases. In unilateral cases, fetal intervention is not recommended. If severe bilateral hydronephrosis is present and evidence exists of dysplastic kidney or renal agenesis, and if the fetus is older than 30 weeks' gestation, then delivery should be considered after administering corticosteroid therapy to promote fetal lung maturation. In cases of bladder outlet obstruction, intervention by shunting of the bladder can be considered after sampling fetal urine to assess kidney function. Parents should meet with a pediatric urologist for prenatal consultation.

### **Ureterocele**

Ureterocele is a cystic dilation of the intravesicular portion of the ureter—that is, the distal end at the junction of the bladder. Ureteroceles can be classified as simple or ectopic. Simple ureteroceles are at the normal location of the ureteral orifice in the trigone of the bladder. These are more commonly found in adults and may be associated with a varying degree of obstruction. In ectopic ureteroceles, the ureteral orifice is in an ectopic position, usually distal to the trigone. It can be associated with a duplex collecting system (75%). Ectopic ureteroceles tend to be unilateral, but are bilateral in 10% to 20% of cases. The incidence is 1 per 5,000 LBs.

Unilateral hydronephrosis is often noted first on ultrasound examination, with the key feature being a dilated upper pole of the kidney with a normal lower pole. A crescent-shaped line may be seen at the base of the bladder, demonstrating the prolapsing ureterocele. The ureterocele itself is of no consequence unless it is causing bladder outlet obstruction. If obstruction is noted, then bladder decompression via needle aspiration may be indicated. Parents should meet with a pediatric urologist.

### **Multicystic Dysplastic Kidney**

Multicystic dysplastic kidney is an extreme form of dysplasia of the kidney characterized by large dilatations

of the collecting tubules with an atretic ureter. The kidney essentially consists of a group of cysts containing some connective tissue, with no real renal tissue present. Up to 80% of cases are unilateral. The incidence is reported as between 1 per 1,000 to 1 per 4,500 LBs. Multicystic dysplastic kidney is thought to arise from an early error in the development of the mesonephric blastema leading to an early obstructive uropathy.

On ultrasound examination, a cystic paraspinal flank mass is noted. Multiple cysts of varied size exist at the periphery of the kidney. They start out small but will usually get bigger over time. The overall kidney size may be either large or small. If unilateral, hypertrophy of the contralateral kidney may then be noted as a compensatory mechanism. A thorough ultrasound examination should be performed to assess for associated genitourinary and nongenitourinary anomalies. Amniocentesis should be performed because of this disorder's association with chromosomal abnormalities.

The prognosis depends on the presence of other anomalies, particularly in cases of unilateral dysplasia. If no other anomalies are present and the contralateral kidney is normal, then the prognosis is excellent. Bilateral severe cysts result in fetal death. If partial dysplastic involvement of both kidneys is found, then renal impairment may eventually occur.

### Renal Agenesis

Renal agenesis is the congenital absence of either one or both kidneys. At 4 to 6 weeks' gestation, the metanephros fails to develop, which leads to the complete absence of the kidney. The incidence of unilateral agenesis is 1 per 1,000 LBs, and of bilateral agenesis is 12 per 100,000 LBs.

The diagnosis of bilateral renal agenesis is made when severe oligohydramnios or oligohydramnios is noted after 14 weeks' gestation, along with the inability to visualize the fetal bladder or kidneys. Visualization can be difficult in the absence of amniotic fluid. Amnioinfusion may be considered, in which sterile saline is infused into the uterus using the same method as in amniocentesis. This procedure is helpful to rule out ruptured membranes, and it aids in the anatomic survey.

No fetal intervention is available. Up to 40% of fetuses with bilateral renal agenesis are stillborn; the remaining fetuses die shortly after birth from respiratory or renal complications. Unilateral agenesis may be asymptomatic and consistent with life. Unilateral renal agenesis may have other associated birth defects, most commonly involving the genitourinary system. Girls should eventually undergo pelvic ultrasound to assess for müllerian anomalies.

### Umbilical Cord

The umbilical cord normally has 2 arteries and 1 vein. In the case of a single umbilical artery, also known as a 2-vessel cord, one of the arteries is congenitally absent. Its incidence is 0.5% to 0.9%.

The umbilical arteries develop from the allantois, which is a diverticulum of the yolk sac. Single umbilical artery occurs as a result of either primary agenesis of one of the umbilical arteries, secondary atresia of one of the arteries, or persistence of the common allantoic or umbilical artery.

A detailed ultrasound evaluation is necessary to assess for other anomalies, and if they are present, then amniocentesis should be performed, because the risk of aneuploidy is increased. If the workup is normal, then serial sonograms should be performed for the remainder of the pregnancy because this disorder is associated with IUGR.

### Skeletal Defects

#### Achondroplasia

Achondroplasia is a form of short-limbed dwarfism and is the most common form of nonlethal skeletal dysplasia. It is characterized by rhizomelic limb shortening with macrocephaly. Endochondral ossification is decreased. Bones that are initially formed from cartilage, such as long bones, are affected. The incidence is 1 per 26,000 LBs.

On ultrasound examination, all the long bones are noted to be shortened (less than the third percentile), particularly the femur. This finding is first notable at 21 to 27 weeks' gestation. The overall shape of the bones is normal. Additional findings include a large head (macrocrania), an abnormal profile caused by frontal bossing, and a protruding abdomen. Development of mild polyhydramnios may also occur in the third trimester. Once achondroplasia is detected, echocardiography and karyotyping should be performed to rule out other conditions. Finding the *FGFR3* mutation on amniocytes can confirm the diagnosis. A fetus with macrocrania near term may require delivery by cesarean; therefore, serial sonograms should also be performed.

Intelligence and life span are normal. Neurologic sequelae remain a risk because of spinal cord compression. Homozygosity for achondroplasia is lethal, resulting in stillbirth or neonatal death from respiratory failure.

#### Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a heterogeneous group of brittle bone disorders and is characterized by a tendency to develop spontaneous fractures, both before and after birth. Most individuals are heterozygotes, and most types of OI are caused by type I collagen abnormalities. Osteogenesis imperfecta is considered a heritable condition because it results from genetic changes. Most people with OI (>90%) have a mutation in one of the two copies of the genes (*COL1A1* or *COL1A2*) that carry instructions for making type I collagen—the protein “scaffolding” of bone and other connective tissues. The remaining 10% of cases of OI result from a spontaneous dominant mutation.

Our understanding of this disease from a genetic level has not only allowed for more accurate diagnosis of the disease using collagen molecular testing, but also has allowed us to understand the manifestations of the disease, even as early as the prenatal period. Features that can be seen on prenatal ultrasonography, usually between 14 and 18 weeks' gestation (for types II and III OI; type I cannot be easily diagnosed), include increased NT; reduced echogenicity of bones; multiple fractures of the long bones, ribs, and skull at various stages of healing; and bowing of the long bones (with or without shortening). Once there is a

concern for OI via prenatal ultrasonography, the diagnosis can be made from either CVS demonstrating abnormal type I collagen via electrophoresis, or amniocentesis, which obtains fetal DNA for molecular analysis. Because most mutations will involve COLA1/COLA2 genes, testing is centered around the identification of these genes followed by examination of the other aforementioned genes.

Type I OI, the most common and mildest form of the disease, is nondeforming and results in patients attaining close to a normal height. However, vertebral fractures are common and can lead to mild scoliosis. Patients typically have blue sclera and, infrequently, dentinogenesis imperfecta. Fractures are rarely observed at birth, but begin with ambulation and subsequent falls during juvenile development, then commonly decrease following puberty.

Type II OI is the most severe form, resulting in death in the perinatal period. Infants typically die within weeks from pulmonary insufficiency or cardiac complications. These individuals exhibit multiple intrauterine rib and long bone fractures, and severe skeletal deformities, which eventually result in respiratory failure. Bone histology reveals a marked decrease in both cortical bone thickness and the amount of trabecular bone.

Type III OI is the most severe nonlethal form of the disease. It is characterized by severe progressive skeletal deformities, often starting from birth. Fractures may be present in utero and are very common during the growing period. The incidence of fractures remains high even in adult life. Individuals have severely short stature and, because of their deformities and bone fragility, are often confined to a wheelchair for life. Scoliosis can lead to respiratory problems, which have been identified as a leading cause of death in this patient group. Dentinogenesis imperfecta is often present.

Type IV OI is the most clinically diverse group. The phenotype can vary from severe to mild, with the more severely affected patients presenting with fractures at birth, exhibiting moderate skeletal deformities, and attaining a relatively short stature.

Type V OI is moderately deforming, and patients exhibit moderate to severe bone fragility. Blue sclera and dentinogenesis imperfecta are not present. There are 3 distinctive features: the frequent development of hypertrophic calluses at fracture sites; the calcification of the interosseous membranes between the bones of the forearm; and the presence of a radio-opaque metaphyseal band immediately adjacent to the growth plates on radiograph. Upon histologic examination, the bone organization has an irregular mesh-like appearance, clearly distinct from the normal lamellar pattern. The calcified interosseous membrane often severely limits the pronation/supination of the hand and may lead to secondary dislocation of the radial head. Importantly, the hyperplastic callus that may develop after fractures or surgical interventions may mimic osteosarcoma. Magnetic resonance imaging and computed tomography can be useful to make the distinction in unclear cases. Patients with Type V OI seem to represent 4% to 5% of the OI population seen in hospitals.

Type VI OI patients also present with moderate to severe skeletal deformities, and do not have blue

sclera or dentinogenesis imperfecta. Distinctive histologic features are the fishscale-like appearance of the bone lamellae and the presence of excessive osteoid accumulation on bone-forming surfaces. The latter suggests a mineralization defect reminiscent of osteomalacia, but there is no abnormality in mineral homeostasis, and growth plate mineralization proceeds normally. Inheritance is autosomal recessive. Type VI OI may be present in approximately 4% of moderately to severely affected OI patients.

Type VII OI patients also have moderate to severe skeletal deformities and bone fragility, and lack blue sclera and dentinogenesis imperfecta. Their distinctive clinical feature is a rhizomelic shortening of the humerus and femur. Coxa vara may be present even in infancy. To date, this disorder has only been observed in a community of Native Americans in northern Quebec, where it exhibits autosomal-recessive inheritance. The disease has been assigned to chromosome 3p22-24.17, co-localizing with the gene encoding CRTAP, a cartilage-associated protein, whose expression is 90% reduced in homozygote patients.

The family history will provide clues about diagnosis. If OI is suspected prenatally and no known family history is found, then type II must be considered. Confirmation of diagnosis can be made by biochemical and histologic testing. For the nonlethal forms, cesarean delivery may be of benefit to decrease the risk of fracture.

## Extremities

### Arthrogryposis

Arthrogryposis is a term to describe a group of disorders that are characterized by congenital nonprogressive joint contractures at multiple sites. The muscles in the affected areas are replaced with fat and fibrous tissue. The incidence is 1 per 3,000 to 4,000 LBs.

Four major causes of contractures have been identified. The first is an abnormality in muscle tissue. The second is abnormal nerve function or innervation. The third is an abnormality of connective tissue. The fourth is a mechanical limitation of movement. Clinical features include joint rigidity, short and tight muscles, and joint dislocation.

On ultrasound examination, the diagnosis is made by observation of malposition of the fetal limbs. The bones are morphologically normal, but the range of motion is limited. A detailed ultrasound evaluation should be performed to rule out other associated anomalies and to further delineate the case into possible syndrome categories. Karyotyping should be offered to rule out chromosomal abnormalities.

### Congenital Talipes Equinovarus

Congenital talipes equinovarus (CTEV), or club foot, is a term used to describe an abnormal positioning of the foot and is characterized by equinus and inversion of the foot with associated abnormalities in the musculature of the lower leg. The incidence is 1 per 1,000 LBs with a 2:1 male-to-female predominance; 50% of affected infants will have bilateral foot deformities.

The fetal lower limb begins movement between 9 and 11 weeks' gestation. If neurologic or muscular abnormalities are present, then limb movements may

be impaired, and joints will eventually become stiff and even contracted.

Talipes equinovarus deformities can be identified as early as 16 weeks' gestation by antenatal sonography. On ultrasound examination, the 2 long bones of the lower leg can be seen at the same time as the lateral aspect of the feet; the feet are in a fixed position—plantar flexed, internally rotated, and adducted. Most cases of clubfoot are isolated and idiopathic. If other anomalies are associated, then a syndrome may be present. Although offering amniocentesis is controversial when the finding is isolated, it should be performed if other anomalies are suspected. Parents should consult a pediatric orthopedic surgeon.

### Twins

It is important to determine the chorionicity of twin pregnancies. Monochorionic pregnancies carry a unique risk for twin-twin transfusion syndrome (TTTS) and its associated morbidity and mortality, and thus require greater surveillance throughout the pregnancy. Chorionicity can be determined on both first- and second-trimester ultrasound. This is accomplished via examination of the membrane at its insertion into the placenta. In a dichorionic gestation, the membrane is thick (>2 mm) and its insertion seems triangular and is described as the *lambda* or *twin peak* sign. In a monochorionic gestation, the membrane is thin and inserts flatly into the placenta and is described as the *T* sign.

### Intrauterine Growth Restriction

IUGR is a condition defined as birth weight below the tenth percentile at a given gestational age. The causes of IUGR are fetal, maternal, or placental. At the time of diagnosis, a detailed ultrasound examination is performed to determine whether any anomalies are present. Echocardiography is useful because cardiac anomalies are significantly associated with IUGR. Amniocentesis should be offered, particularly if IUGR is diagnosed early in gestation, because aneuploidy is also strongly associated with IUGR. Infection studies (TORCH [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex]) can be requested at the time of amniocentesis. Amniotic fluid volume is also assessed as a determination of placental function. Doppler ultrasound may also be performed to ensure fetal well-being. Fetuses are assessed by serial sonograms, because the diagnosis of IUGR carries an increased risk of fetal death.

## Chapter 83

# FETAL INTERVENTIONS

Garfield Clunie, MD

## INTRODUCTION

The field of prenatal diagnosis has seen a rapid advancement over the past decade with the improvement in high-resolution ultrasound, including 3D and 4D technologies, fetal magnetic resonance imaging (MRI), improved maternal serum screening for aneuploidy, and genetic prenatal diagnosis. In large part because of these advances, most structural abnormalities previously diagnosed in the newborn period are now diagnosed prenatally. Certain anomalies may lead to fetal deterioration and impairment of normal organ development during the course of the pregnancy, subsequently leading to worse postnatal outcomes in some instances. For these conditions, fetal intervention, if available, may provide a viable option for fetuses otherwise at risk for serious morbidity or mortality.

In the past, parents' options were narrow: termination of pregnancy (if an anomaly was diagnosed early enough) or treatment of the newborn after delivery. Treatment for Rh isoimmunization in the early 1960s was the first example of a successful medical intervention in the fetus, but it was not until the 1980s that the field began to expand. Because of the high rate of complications from early interventions such as open fetal surgery, fetal intervention was initially reserved for conditions that, if left untreated, would lead to a high chance of perinatal mortality and morbidity. Since that time, the field of fetal intervention has greatly progressed, leading to the creation of more alternatives, including minimally invasive approaches, for pregnancy management when a fetus is found to

**Table 83-1** Fetal Interventions

TYPE OF INTERVENTION	DESCRIPTION	CLINICAL INDICATIONS
Open surgery	<ul style="list-style-type: none"> <li>• Hysterotomy under general anesthesia</li> <li>• Requires 3–7 days postoperative hospitalization</li> <li>• Obligates cesarean delivery</li> <li>• Preterm labor and preterm delivery are associated risks</li> </ul>	<ul style="list-style-type: none"> <li>• Large congenital lung malformations</li> <li>• Sacrococcygeal and cervical teratomas</li> <li>• Myelomeningocele repair</li> <li>• EXIT procedure</li> <li>• CDH (EXIT to ECMO)</li> <li>• CPAM (EXIT lobectomy)</li> </ul>
Endoscopic fetal surgery	<ul style="list-style-type: none"> <li>• Fetoscopic surgery using small endoscopes</li> <li>• Performed either percutaneously or through a small laparotomy incision</li> <li>• Preterm labor is a risk but less so than with open surgery</li> </ul>	<ul style="list-style-type: none"> <li>• Balloon occlusion trachea (CDH)</li> <li>• Laser ablation vessels (TTTS)</li> <li>• Cord ligation or division</li> <li>• Cystoscopic ablation posterior urethral valves</li> </ul>
Fetal image-guided surgery	<ul style="list-style-type: none"> <li>• Sonography-guided endoscopic surgery performed through a percutaneous or small laparotomy incision</li> <li>• Performed under regional (epidural, spinal) or local anesthesia</li> <li>• Least invasive, although a risk for preterm labor exists</li> </ul>	<ul style="list-style-type: none"> <li>• Amniotic bands division</li> <li>• Amnioreduction or amnioinfusion</li> <li>• Fetal blood sampling</li> <li>• Twin-reversed arterial perfusion (acardiac or acephalic twin)</li> <li>• Vesicoamniotic shunts for obstructive uropathy</li> <li>• Pleural (thoracic) amniotic shunts for pleural effusions or hydrothorax</li> <li>• Cord monopolar cautery</li> <li>• Balloon dilation aortic stenosis</li> </ul>

CDH, congenital diaphragmatic hernia; CPAM, congenital pulmonary airway malformation; ECMO, extracorporeal membrane oxygenation; EXIT, ex utero intrapartum treatment; TTTS, twin-to-twin transfusion syndrome.

have an abnormality. As these less invasive techniques have become more widespread, the procedural complication rate has also decreased, leading to the application of fetal interventions for a wider variety of fetal conditions.

## TYPES OF FETAL INTERVENTIONS

The first fetal intervention attempted was a fetal transfusion for hemolytic disease in the 1960s. The first open fetal surgery cases, performed during the 1980s, were for bladder outlet obstruction. Open fetal surgery techniques frequently involve administration of inhalation anesthetics to the pregnant woman, to provide deeper than usual sedation in order to achieve uterine hypotonia. Tocolytics are often necessary as well. A hysterotomy is performed, and the fetal malformation is repaired. This type of surgery is associated with a high rate of preterm labor and preterm premature rupture of membranes, and the mother usually needs to be hospitalized for recovery and, as needed, tocolysis.

With the advent of minimally invasive techniques such as fetal endoscopy and ultrasound-guided fetal surgery, maternal recovery time and preterm labor rate have decreased. Fetal endoscopy, also known as fetoscopy, is based on preserving fetal homeostasis by protecting the intrauterine environment. The surgery is performed by introducing a 3- to 5-mm trocar into the uterine cavity to allow for placement of endoscopes or fetoscopic instruments.

Ultrasound-guided fetal surgery, also termed fetal image-guided surgery, is a needle-based or percutaneous procedure. It is the least invasive technique and

can be performed under local anesthesia. This type of intervention was first used for amniocentesis and percutaneous umbilical blood sampling. It can now be used to place a catheter in the fetal bladder, abdomen, or chest and to provide radiofrequency ablation for complications associated with monochorionic multiple gestations. This chapter describes the most common fetal interventions available to treat a variety of fetal abnormalities (Table 83-1).

## FETAL INTERVENTIONS FOR SPECIFIC ABNORMALITIES

### Bladder Outlet Obstruction

Obstructive uropathy is known to affect from 1 in 20 to 1 in 1,000 births and can be the result of ureteropelvic junction obstruction or urethral obstruction. In male fetuses, this obstruction can be seen most commonly with posterior urethral valves. Other causes include urethral atresia and urethral hypoplasia. Lower urinary tract lesions seem to have a higher association than upper urinary tract lesions with morbidity. This abnormality can lead to severe hydronephrosis, progressive renal damage, subsequent decreased fetal urine output, and oligohydramnios. When the abnormality occurs early in the second trimester, pulmonary hypoplasia may result, leading to high rates of in utero or early postnatal demise.

Initially, affected fetuses are monitored with serial ultrasounds. If both kidneys are noted to be affected and the fetus is male, then fetal intervention may be considered to allow for relief of the obstruction and for accumulation of amniotic fluid for fetal lung development.

Because pulmonary hypoplasia results from oligohydramnios, the presence of oligohydramnios is an important consideration in deciding when to intervene. Before intervention, an intensive workup is required to determine whether the fetus is an appropriate candidate for therapy. This includes determination of fetal karyotype and careful sonographic evaluation for any additional abnormalities and to characterize the fetal kidneys. Poor prognostic indicators include echogenic kidneys, kidneys with multiple cysts, and evidence of perinephric urinoma, which indicates rupture of the urinary tract. Finally, fetal urine must be sampled for electrolytes and  $\beta$ -microglobulin. Healthy fetuses usually produce hypotonic urine, whereas renal damage is associated with salt wasting and can lead to isotonic urine production. Fetuses with evidence of isotonic urine are not good surgical candidates because of impaired kidney function. Fetal urine is sampled by draining the fetal bladder in a method similar to amniocentesis. A needle is introduced into the fetal bladder, and the bladder is completely drained. This procedure is repeated twice more, 48 to 72 hours apart. The third sample provides the most accurate assessment of fetal renal function.

The first fetal intervention used for treatment of bladder outlet obstruction was open fetal surgery. In 1982, Harrison and colleagues published the first case report of bilateral ureterostomies performed at 21 weeks' gestation. The surgery itself was successful at reversing the hydronephrosis and bladder distention, and the pregnancy continued until 35 weeks. However, the infant died 1 day after delivery as a result of severe pulmonary hypoplasia.

Ultrasound-guided placement of a catheter for vesicoamniotic shunting involves placement of a tube into the fetal bladder so that urine can flow from the bladder into the amniotic fluid. The most common complication from this procedure, a blocked or dislodged catheter, occurs in up to 40% to 50% of cases, which can lead to impaired shunt function with further worsening of the obstructive uropathy. Although there remains a small increased risk for preterm labor and premature preterm rupture of membranes, ultrasound-guided fetal surgery is far less risky than either open fetal surgery or fetoscopy. In addition, this technique is easier to perform and is more widely available than fetal surgery. However, neither open fetal surgery nor vesicoamniotic shunting addresses the structural anatomic problem (eg, posterior urethral valves). Perinatal mortality rate remains at 40% to 50%, most commonly resulting from pulmonary hypoplasia. Additionally, surviving fetuses have severe bladder abnormalities after birth. Less than 50% of those successfully treated will have normal renal function after birth. Additionally, more than 50% of surviving infants will have severely compromised growth secondary to chronic renal failure. Because of their significant bladder dysfunction, these infants are also poor renal transplantation candidates. Although these fetal interventions may reduce the pulmonary sequelae associated with bladder outlet obstruction and severe oligohydramnios, they do not address the renal sequelae.

The fetoscopic approach involves introducing a small trocar sheath through which a small fiberoptic

endoscope passes into the fetal bladder to identify and possibly ablate proximal urethral obstructions. Reported cases of fetoscopic ablation of posterior urethral valves have been technically successful but are still associated with a high rate of obstetric complications. Long-term safety and efficacy data have yet to be established. After birth, these neonates require follow-up with renal ultrasound and voiding cystourethrograms to determine whether further intervention is necessary.

### **Congenital Diaphragmatic Hernia**

Congenital diaphragmatic hernia (CDH) has been theorized to result from the failure of the normal closure of the pleuroperitoneal folds 4 to 10 weeks after fertilization. It has also been attributed to genetic or environmental factors that affect differentiation of mesenchymal cells during formation of the diaphragm. Most CDH occurs sporadically, with no identifiable familial association. Most of these hernias occur on the left side, and the disorder occurs in approximately 1 in 2,200 to 1 in 3,000 births. Herniation of abdominal contents into the thoracic cavity in the early second trimester causes compression of the hemithorax and can lead to severe pulmonary hypoplasia caused by the interruption of pulmonary development at an early stage of development, thus impairing branching morphogenesis and development of bronchioles and alveoli. Most of these infants are born with a degree of fixed lung hypoplasia and pulmonary hypertension. The severity of lung hypoplasia and secondary respiratory failure can be reduced and potentially prevented if fetal repair is performed early. Current advances in neonatal care have improved outcomes and survival rates for these infants. However, some are born with severe fixed hypoplasia and inadequate gas exchange. Aspects of the clinical presentation and features of congenital diaphragmatic hernia as well as treatment options and outcomes are discussed in Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn; Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn; and Chapter 116, Health and Developmental Outcomes of Selected Medically Complex Neonates.

Antenatal evaluation requires a detailed ultrasound and a fetal echocardiogram to screen for other defects, as well as fetal karyotype to rule out aneuploidy. Diagnosis of CDH at less than 25 weeks' gestation with liver herniation is associated with the poorest prognosis. Liver herniation into the hemithorax is associated with a postnatal survival rate of less than 50%, whereas the absence of liver in the hemithorax is associated with a 90% survival rate. Similarly, diagnosis after 25 weeks' gestation has a near 100% survival rate compared with 56% when the diagnosis is made at or before 25 weeks' gestation. The lung-to-head ratio (LHR), which is the ratio of the lung area contralateral to the hernia defect to the fetal head circumference, has also been shown to be predictive of survival. An LHR of less than 0.6 is associated with a 0% survival rate compared with 100% survival in fetuses with an LHR of more than 1.35. LHR has been validated for use in fetuses between 23 and 26 weeks' gestation. The reliability of LHR for fetuses outside of this range, particularly at greater than 26 weeks' gestation, is debatable. For

those fetuses outside of this gestational age range, an association with increased postnatal mortality has been demonstrated for late-gestation fetal MRI-derived low total lung volume and the need for extracorporeal membrane oxygenation (ECMO) support. Although maturation and development of the lungs continues after birth, fetal lung growth should be complete by 34 weeks' gestation. Fetal MRI for total lung volume performed after 34 weeks' gestation may be used to identify, counsel, and develop a treatment plan for patients diagnosed with fetal CDH (eg, transfer to facility with ECMO capabilities; counseling regarding neonatal mortality rate).

For those fetuses with the poorest prognosis, fetal surgery may be offered as an alternative. The goal of fetal intervention is to assist with the development of the lungs so that these neonates can breathe after birth. The first attempted fetal intervention for CDH was open fetal surgical repair of the diaphragmatic defect. A National Institutes of Health (NIH)-sponsored prospective randomized clinical trial found no benefit to fetal surgery over conventional postnatal care. However, preterm delivery rates were higher among the fetal surgery patients. Focus then shifted to interventions aimed at correcting the pulmonary hypoplasia before birth. Occlusion of the fetal trachea in animal models of CDH demonstrated that tracheal occlusion could reduce the pulmonary hypoplasia associated with CDH. With blockage of the trachea, the fluid produced by the fetal lung remains in the lungs, resulting in expansion and accelerated maturation of the lungs.

Various methods have been described for tracheal occlusion and may be considered for fetuses with very severe CDH in which either the liver is herniated into the chest cavity or the LHR is low. Minimally invasive fetoscopic techniques have since been developed for tracheal occlusion. One approach uses fetoscopic neck dissection to attach obstructing clips to the trachea, a method complicated by the fine dissection required to bring the trachea into view. This fetoscopic approach has been modified to allow for endoscopic placement of a detachable balloon in the trachea that can be deflated after delivery. These newer, less invasive techniques have improved survival rates while decreasing preterm labor rates, the need for tocolytic therapy, and length of maternal hospitalization.

### **Congenital Pulmonary Airway Malformation**

Congenital pulmonary airway malformation (CPAM), formerly known as congenital cystic adenomatoid malformation (CCAM), is a rare abnormality of the lower respiratory tract. The incidence of CPAM is only approximately 1 in 25,000 to 1 in 35,000 pregnancies. CPAM is a congenital cystic lesion that occupies space in the lung field as a result of abnormalities that occur at varying stages of pulmonary development. Although usually unilateral or lobar, CPAMs are found in equal distribution among the right and left lung and in all lobes and may involve multiple lobes. CPAMs can decrease in size, remain stable, or increase in size. CPAMs may lead to nonimmune fetal hydrops by causing a mediastinal shift, compression of the vena

cava, and compromised venous return to the heart. Affected fetuses can have associated polyhydramnios as a result of increasing intrathoracic mass size, leading to esophageal compression and impaired swallowing. In a review of 17 cases of CPAM, the presence of nonimmune fetal hydrops was the only significant negative predictor of outcome, and its presence was associated with a 100% perinatal mortality rate in that series.

CPAMs have been divided into 5 different types based on histologic characteristics (type 0 through type IV). Thus, to confirm the type, postnatal histology is needed. Adzick and colleagues proposed a modification to Stocker's classification of CPAMs based on anatomy and appearance to assist in predicting prenatal outcome. Macrocystic CPAMs have single or multiple cysts more than 5 mm in diameter, and microcystic CPAMs have cysts that are less than 5 mm in diameter, giving them a more homogeneous appearance. Microcystic lesions increase the risk for development of hydrops. Because they can be quite large, microcystic lesions can also cause mediastinal shift, pulmonary hypoplasia, and polyhydramnios.

Before surgical intervention, a detailed ultrasound with color-flow Doppler to demonstrate or exclude systemic blood supply is necessary to confirm the diagnosis and to identify any additional structural abnormalities. Fetal echocardiogram is also recommended because of the increased incidence of associated cardiac anomalies, particularly truncus arteriosus and tetralogy of Fallot. Fetal MRI may be useful for distinguishing CPAM from other abnormalities, such as bronchopulmonary sequestration (BPS) or CDH. Without antenatal surgical intervention, most fetuses with large CPAMs resulting in hydrops will die in utero or in the early neonatal period. However, there are reports of resolution of the hydrops caused by CPAM after maternal steroid administration. Nevertheless, further study is needed to confirm true causality.

The CPAM volume ratio (CVR) is a useful prognostic tool. It is obtained by dividing the CPAM volume by the head circumference, to correct for gestational age. A CVR of greater than 1.6 is associated with an 80% risk for hydrops, whereas a CVR of less than 1.6 carries a 2% risk for hydrops. Fetal surgical resection of the CPAM by open fetal surgery in fetuses with hydrops has been shown to be successful in resolving hydrops, promoting in utero lung growth, and improving perinatal survival rates. Other techniques include thoracocentesis and placement of a thoracoamniotic shunt to decompress large cysts, serial aspirations for hydrops, and administration of a short course of prenatal steroid therapy. If the fetus has a large lesion, a specialized ex utero intrapartum treatment (EXIT) procedure may be considered at delivery. This procedure involves the baby being delivered and remaining attached to the placenta while the CPAM is surgically resected or until ECMO support is provided.

### **Sacroccygeal Teratoma**

Sacroccygeal teratoma (SCT) is the most common fetal neoplasm and one of the most common tumors in

newborns. With an overall incidence of 1 in 40,000 live births and a birth prevalence of 1 in 21,700 to 1 in 27,000 live births, it is more common in females than males (4:1 ratio). In the past, it was suggested that SCT was of germ cell origin. However, more recently, SCT has been thought to arise from a totipotent somatic cell originating from Hensen's node. SCTs are classified into 4 types based on the location of the tumor and degree of extension. This classification, described by Altman, is based on the intra-abdominal extent versus the external extent of the lesion. Although many of these tumors may attain a large size in utero without fetal compromise, in some cases arteriovenous shunting through the tumor can lead to high-output cardiac failure and fetal hydrops. Most studies have shown that the presence of hydrops and placentomegaly is associated with the poorest prognosis, particularly when diagnosed before 30 weeks' gestation. Some studies have shown the highest risk for fetal death associated with the most vascularized tumors, regardless of size, and in the presence of fetal hydrops. In a retrospective review of 12 fetuses diagnosed with SCT, tumor volume-to-fetal weight ratio (TFR) performed between 16<sup>6</sup>/<sub>7</sub> and 32 weeks' gestation was predictive of fetal outcome. A cutoff of TFR greater than 0.12 predicted a poor outcome, defined as development of hydrops or fetal or neonatal demise, whereas TFR less than 0.12 before 24 weeks' gestation predicted an uncomplicated prenatal course with a 100% survival rate.

Fetal hydrops, polyhydramnios, and associated placentomegaly may cause a maternal *mirror syndrome*, in which the mother develops hypervolemia, hemodilution, pulmonary edema, and elevated blood pressure. This condition can be life threatening to the mother and often requires delivery for maternal symptomatic relief. SCTs may also complicate delivery of the fetus resulting from dystocia or traumatic hemorrhage at the time of vaginal delivery. Some have suggested a cutoff of more than 5 cm or a volume of 750 cm<sup>3</sup> as an indication for elective cesarean delivery. Prematurity is another complication of SCTs, usually secondary to preterm labor from polyhydramnios. SCTs may also be associated with abnormalities of the central nervous, cardiac, urogenital, or musculoskeletal systems.

Many SCTs are identified in utero on prenatal ultrasound. SCTs contain solid and cystic components and are highly vascularized. Although 3D ultrasound and MRI may aid in diagnostic imaging, particularly in determination of location, content, and degree of extension of the tumor, ultrasound with Doppler studies remains the primary imaging method. Affected fetuses need detailed serial ultrasounds and echocardiograms to assess growth and to evaluate for the development of fetal hydrops.

Open fetal surgery before 30 weeks' gestation has been successfully performed in fetuses that have developed hydrops. Since the first successful case in 1997, 3 additional cases of open surgery have been performed. Although fetal surgery has been successful at antenatal resection of SCTs, it is also associated with a high preterm labor rate and significant maternal and fetal morbidity and mortality. Based on these earlier cases, the Children's Hospital of Philadelphia developed

criteria for open fetal surgical resection, which take into account any maternal contraindications, the gestational age of the fetus, staging of the teratoma, the presence of hydrops, the presence of significant placentomegaly, fetal karyotype, fetal cardiac status, and the presence of maternal mirror syndrome.

Less invasive methods have since been described that involve inserting a needle or probe into the blood vessels that feed into the tumor and ablating the vessels so that the high-velocity blood flow is disrupted, such as with radiofrequency ablation or thermocoagulation of tumor vessels. Reported cases have had varying degrees of success. Some cases were complicated by fetal hemorrhage, significant skin necrosis, and fetal muscle or hip joint and pelvic bone injury requiring additional surgery after delivery. Despite the theoretical benefit from prenatal intervention for SCTs, particularly in cases with large, well-vascularized tumors and hydropic fetuses, none of the fetal interventions performed has been shown to reliably improve outcome or survival, and they have in fact been associated with significant procedure-related morbidity and risk for preterm delivery.

### **Congenital High Airway Obstruction Syndrome**

Congenital high airway obstruction syndrome (CHAOS), first described by Hedrick and colleagues in 1994, is characterized by large echogenic lungs, flattened or inverted diaphragms, dilated airways distal to the obstruction, and fetal ascites or hydrops. The most common etiology of CHAOS is laryngeal atresia, although isolated tracheal or subglottic atresia has been described. The pathognomonic sonographic findings of CHAOS are the manifestations of upper airway obstruction leading to lung expansion caused by the trapping of lung fluid. This leads to flattening, and ultimately inversion, of the diaphragm and dilation of the upper airways distal to the obstruction. Experience from fetal interventions to treat CDH has demonstrated that the upper airway obstruction must be complete and occur early in development in order to produce the CHAOS phenotype.

The natural history of CHAOS is not well defined. Many affected fetuses die in utero, and many who survive to delivery die in the early neonatal period. Fetuses diagnosed with CHAOS fall into 1 of 3 categories: complete laryngeal atresia without an esophageal fistula, complete laryngeal atresia with a tracheoesophageal fistula, and near-complete high upper airway obstruction. Approximately one-third of affected fetuses will develop progressive nonimmune hydrops and die in utero. In another one-third of fetuses, the lesion will spontaneously perforate through the tracheal or laryngeal atresia or less commonly decompress through a tracheoesophageal fistula. The remaining one-third of affected fetuses tolerate hydrops reasonably well and remain hydropic until 30 to 32 weeks' gestation, at which point preterm labor or fetal distress prompts the need for an EXIT procedure. In cases in which CHAOS is caused by a thin web or laryngeal cyst, spontaneous rupture of the lesion can lead to complete resolution of the condition. Fetoscopy has also been used to treat CHAOS because of an isolated tracheal web.

Ex utero intrapartum treatment (EXIT) is a procedure for securing the fetal airway in fetuses at risk for airway obstruction while maintaining placental support. The EXIT procedure has been used for fetuses with head and neck tumors and for placement of a tracheal plug or clip in cases of CDH. In 1998, DeCou and colleagues reported the first case of CHAOS treated successfully during an EXIT procedure at 35 weeks' gestation with bronchoscopic evaluation and placement of a tracheostomy. Since that time, 11 cases have been reported. In these cases, prenatal ultrasound and MRI were used to determine the location and degree of airway obstruction. If the EXIT procedure was deemed possible, laryngoscopy and bronchoscopy were performed at the time of the EXIT procedure before tracheostomy placement. It is important to note, however, that although the EXIT procedure may improve perinatal survival, it does not treat the underlying abnormality, and for many of these patients the lesion is lethal and EXIT will not salvage those fetuses. Parents should be aware of the significant long-term morbidity associated with CHAOS, including long-term tracheostomy, impaired or delayed speech, chronic respiratory problems, and the need for several operations.

### Neural Tube Defects

Open neural tube defects (NTDs) are characterized by midline vertebral defects and are usually associated with the dorsal portion of the lumbosacral spine. Open NTDs develop when the neural tube fails to completely close. When the meningeal sac protrudes through the defect, it is called a meningocele. When the hernia sac contains nerve roots, the NTD is called a myelomeningocele. The most common NTD, myelomeningocele affects from 1 in 1,000 to 7 in 1,000 infants worldwide depending on ethnic, geographic, and nutritional factors. Open NTDs are associated with an increased maternal serum  $\alpha$ -fetoprotein level that is typically detected in the second trimester. On ultrasound, the frontal bones of the calvarium may take on a concave shape, known as the *lemon sign*. Herniation of the cerebellum into the foramen magnum may also be seen as a banana-shaped cerebellum in the posterior fossa, known as the *banana sign*.

NTDs are known to be associated with paralysis, hydrocephalus, intellectual disability, and loss of control of bowel and bladder function. In addition, most fetuses with open spina bifida will develop hindbrain herniation, also known as Arnold Chiari II malformations, which may then lead to hydrocephalus. Without surgical closure of the defect, these infants are at high risk for central nervous system infection. Before delivery, exposure of the spinal elements to the intrauterine environment may lead to progressive damage. Assessing the progression of the neurologic damage associated with these lesions in utero is difficult because distinguishing between active and passive movement of individual segments of the lower extremities on ultrasound can be difficult.

The first attempts at fetal repair were made in 1994 by a fetoscopic approach and were aimed at providing cover and protection to the NTD in utero in order to preserve neurologic function until a more definitive

repair could be performed postnatally. The outcomes of these initial procedures were poor. Of the 4 cases, 2 fetuses died, and the surviving 2 infants showed no benefit from the procedure. In 1998, fetal repair was once again attempted, this time using an open technique. Of these 4 cases, all 4 survived to birth and had no evidence of hindbrain herniation. Two infants ultimately required ventricular shunts. Compared with historical controls, in utero repair of open NTDs has led to a decrease in the number of neonatal shunts needed (86% versus 54%). An NIH-funded randomized clinical trial, the Management of Myelomeningocele Study (MOMS) trial, was published in 2011. This study compared outcomes of in utero repair with standard postnatal repair over a 7-year period from 2003 to 2010. The study was stopped prematurely because of the efficacy of prenatal surgery. Prenatal surgery for myelomeningocele reduced the need for shunting and improved motor outcomes at 30 months. However, prenatal surgery was associated with an increased risk for preterm delivery and uterine dehiscence at delivery. A second phase of this study that is underway, MOMS2, is evaluating the adaptive behaviors (personal and social skills) of the children enrolled in the MOMS trial between 5 and 9 years of age. Additional outcomes will include cognitive and motor functioning, brain morphology and function, and urologic and other spina bifida-associated outcomes and the child's quality of life.

### Amniotic Band Sequence

Amniotic band sequence (ABS) includes a group of sporadic congenital structural anomalies, typically involving the limbs, craniofacial regions, and trunk, which arise secondary to constriction rings or amputations associated with fibrous amniotic bands present within the amniotic cavity. Amniotic bands may be seen sonographically as early as 12 weeks' gestation. However, ABS is more often diagnosed by the effect of the bands on fetal anatomy. Sonographic findings commonly include absent digits or portions of limbs, or less commonly craniofacial, visceral, or body wall defects.

The incidence ranges from 1 in 1,200 to 1 in 15,000 live births and 1 in 70 stillbirths. The exact pathogenesis of amniotic bands is unknown, although current literature and animal models support the theory that these bands form after rupture of the early amnion, resulting in loose bands of amnion, which may then entangle the fetus and lead to vascular or mechanical disruption. The prognosis in ABS depends on the severity of the anomalies and the organ systems involved. As with any procedure that is associated with a significant risk for perinatal morbidity and mortality, fetal intervention for ABS should be performed when salvage of the affected extremity can be achieved. In 1995, Crombleholme and colleagues demonstrated that fetoscopic release of constrictive bands in a lamb model of amniotic band sequence reversed the hydropic changes in the limbs and prevented the other sequelae of banding, including limb shortening, loss of joint mobility, and absence of wool. The first attempt at fetoscopic release in human fetuses was performed at 22 weeks' gestation for a fetus with bilateral cleft lip and bands attached to the face and left upper extremity. Distal limb edema resolved with

minimal residual scarring at the site of band attachment, and the pregnancy continued successfully to 39 weeks. Several cases of fetoscopic release of amniotic bands have since been performed. A review of these cases showed that the most important fetal prognostic factor is the perfusion of the distal portion of the involved extremity. If there is no demonstrable perfusion of the extremity distal to the constriction, the limb may not be salvageable. It is important to note that intervention for ABS is primarily to salvage extremities and will not affect the outcome for more extensive bands where the deformities have already occurred.

### **Monochorionic Twin Gestations**

Monochorionic diamniotic (MCDA) twin gestations by definition share a single placental mass. Compared with dichorionic diamniotic (DCDA) twin pregnancies, monochorionic twins are at risk for specific pregnancy complications, typically secondary to abnormal vascular connections between the 2 fetuses. These anastomoses may be venous-venous (v-v), arteriovenous (a-v), or arterioarterial (a-a). In addition, although the perinatal mortality rate is greater for twins than for singletons, the rate is highest among monochorionic twins compared with dichorionic. Because of the vascular connections within a monochorionic placenta, there are significant risks for permanent neurologic damage to the surviving twin after a fetal death in up to 20% of cases of single twin demise. Certain complications, such as twin-to-twin transfusion syndrome (TTTS), discordant anomalies, and twin-reverse-arterial-perfusion sequence (TRAP), present a unique challenge because of the risk for morbidity and mortality to not only the abnormal fetus but also the normal twin. Treatment of these conditions in the abnormal fetus must take into account the consequences for the surviving twin.

### **Twin-to-Twin Transfusion Syndrome**

Twin-to-twin transfusion syndrome occurs at a rate of 0.1 to 0.9 per 1,000 live births, and the syndrome complicates approximately 10% to 15% of monochorionic pregnancies. The etiology of TTTS is based on the vascular anastomoses within the single placenta and the unequal sharing of blood flow between the 2 fetuses. These anastomoses can lead to the shunting of blood from one fetus (donor twin) to the other (recipient twin) by arteriovenous anastomoses, leading to intrauterine growth restriction in the donor and hydrops in the recipient. Although all monochorionic twins share some vascular connections within the placenta, the number and type of vascular anastomoses determine whether TTTS will develop in an MCDA pregnancy. The syndrome is diagnosed in monochorionic twins when a marked difference is found in amniotic fluid volume between the 2 sacs, leading to polyhydramnios in one sac and oligohydramnios in the other. Significant size discordance (>20%) can also develop between the twins, with the donor twin growing smaller in size. The donor twin is also referred to as the *stuck twin* because of the resulting oligohydramnios and subsequent collapse of the sac around the fetus, limiting its ability to move. The increase in

blood volume in the recipient twin secondary to shunting of blood within the placenta can cause strain on the fetal heart, leading to heart failure and hydrops from the chronic volume overload. If left untreated, fetal death will ensue, usually of the donor twin. The perinatal mortality rate of severe TTTS without intervention ranges from 60% to 100%.

The first minimally invasive technique employed in the treatment of TTTS was serial amnioreduction. The polyhydramnios surrounding the recipient twin leads to excessive uterine distention, impaired uteroplacental blood flow, pressure on the donor twin, and maternal discomfort. Serial reduction of amniotic fluid under ultrasound guidance can be used to help prolong gestation by improving uteroplacental blood flow and easing maternal discomfort. Survival rates among TTTS patients undergoing serial amnioreduction were improved compared with those pregnancies managed expectantly. Care must be taken not to remove too much fluid because placental abruption may occur secondary to the sudden decrease in intra-amniotic pressure. Amniotic septostomy can also be made in the dividing membrane between the 2 fetuses to allow amniotic fluid to flow between the 2 sacs; however, this can create monoamniotic twins, which also carry a high perinatal morbidity and mortality rate.

For the pregnancies that develop severe TTTS early in gestation, an alternative intervention is fetoscopic laser coagulation of anastomotic placental vessels. In 1997, Quintero and colleagues published a staging system for TTTS based on the sonographic appearance of the bladder, the presence or absence of Doppler abnormalities or hydrops, and in utero fetal demise of one or both twins. This staging system was developed to help distinguish those cases most likely to benefit from early fetal intervention. Since the 1990s, this procedure has become available in more centers throughout the United States. Most centers have developed protocols for the workup of these pregnancies before laser coagulation can be considered. Both fetuses must have a normal karyotype, a normal fetal echocardiogram, a detailed ultrasound, and TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) laboratory workup to rule out possible infectious causes. Fetoscopic laser coagulation is considered in early-onset TTTS with a high Quintero stage or after failure of amnioreduction. For this procedure, placental vessels are mapped and all intertwined communicating vessels identified. A thin fiberoptic endoscope is introduced through the wall of the uterus and into the amniotic cavity of the recipient twin. The surfaces of the placental vessels are examined directly, and the abnormal vascular connections are coagulated with a laser. By eliminating the anastomoses, significant shunting of blood flow between the twins is stopped.

Serial amnioreduction and fetoscopic laser ablation have demonstrated the most promise for successful treatment of TTTS. In 2004, a study comparing outcomes after serial amnioreduction versus fetoscopic laser coagulation showed that the laser ablation cohort had a higher likelihood of survival of at least one twin to 28 days of life (76% vs 51%). Additionally, in the laser ablation cohort, the chances of a single

survivor and twin survivors were higher, and the median gestational age at delivery was greater. A Cochrane review of 213 pregnancies complicated by TTTS demonstrated that fetoscopic laser ablation results in few deaths of both infants per pregnancy, fewer perinatal deaths overall, and fewer neonatal deaths compared with serial amnioreduction. Thus, fetoscopic laser ablation is currently the recommended management for early-onset severe TTTS.

### **Twin Anemia-Polycythemia Sequence**

Twin anemia-polycythemia sequence (TAPS) is an atypical chronic form of TTTS that does not present with the requisite polyhydramnios or oligohydramnios but instead presents with a large intertwin difference in hemoglobin. Most cases are diagnosed in the late second or the third trimester. TAPS reportedly occurs in 3% to 6% of otherwise uncomplicated MCDA pregnancies. However, the incidence is up to 13% in pregnancies in which laser surgery has occurred. Lopriore and colleagues reported that residual unidirectional arteriovenous anastomoses after laser surgery for TTTS, which are usually less than 1 mm, lead to gradual development of anemia in one twin and polycythemia in the other twin. This process occurs slowly, which allows for hemodynamic compensation, and is hypothesized to be the reason for the absence of amniotic fluid volume discordance. TAPS may progress to TTTS.

Similar to the detection of fetal anemia in isoimmunization, middle cerebral artery (MCA) Doppler ultrasound evaluation can be used to monitor monochorionic pregnancies for TAPS. Middle cerebral artery peak systolic velocity (PSV) of greater than 1.5 multiples of median (MoM) in one twin (donor) and 0.8 MoM in the other twin (recipient) is used to make the diagnosis. As with TTTS, growth discordance may not be present. Postnatally, 3 measures are required to make the diagnosis. First, the difference between the hemoglobin value of the twins must be 8.0 mg/dL or greater, the reticulocyte ratio must be greater than 1.7, and there must be pathologic evidence of superficial atrioventricular anastomosis. Although the optimal treatment of TAPS has yet to be determined, repeat laser, fetal transfusion, and selective feticide are among the options.

### **Twin Reversed Arterial Perfusion Sequence**

Twin reversed arterial perfusion (TRAP) sequence affects approximately 1 in 35,000 live births and arises from abnormal arterial-to-arterial anastomoses on the placental surface. Because of this abnormal sharing, one twin (acardiac twin) receives all of the deoxygenated blood from the other twin (pump twin). As the deoxygenated blood from the pump twin enters the acardiac twin, normal developmental processes are interrupted, leading to atrophy, usually of the upper body (acardia acephalus). However, because of the anastomotic vessels within the placenta, this acardiac twin is sustained by the pump twin. As in TTTS, TRAP sequence can lead to in utero cardiac failure of the normal twin and eventual fetal death. If left untreated, the mortality rate for the pump twin is 50% to 75%, particularly if the acardiac twin is greater than 50% of

the size of the pump twin. Without intervention, even those fetuses who survive to delivery have significant long-term morbidity.

Treatments for TRAP sequence are aimed at disrupting the vascular connections supporting the acardiac twin in order to prevent the complications to the pump twin associated with high-output cardiac failure. Several fetal interventions have been used, including fetoscopic and ultrasound-guided laser ablation, umbilical cord ligation, bipolar or monopolar ultrasound-guided thermocoagulation, and ultrasound-guided radiofrequency ablation.

Fetoscopic laser ablation, as described previously, involves insertion of a fiberoptic endoscope into the uterus and ablation of the vessels supplying the acardiac twin. Alternatively, this procedure may be performed under ultrasound guidance without the use of a fetoscope. Umbilical cord ligation involves the placement of 2 or 3 trocars into the amniotic cavity, insertion of an endoscope to locate the umbilical cord supplying the acardiac twin, and suture ligation of the cord. Cord ligation has also been performed using ultrasound guidance alone with a single trocar for placement of the suture. The technique for monopolar thermocoagulation involves placement of a wire electrode under ultrasound guidance into the acardiac twin and coagulation of the aorta using monopolar energy. Bipolar cord coagulation requires use of a single trocar for insertion of a small-diameter bipolar coagulating forceps that is used to grasp the cord supplying the acardiac twin. In centers experienced in this procedure, bipolar cord coagulation is associated with a high success rate, low rate of complications, and short operative time. Radiofrequency ablation is performed using local anesthesia. A 3-mm radiofrequency ablation needle is placed percutaneously into the abdomen of the acardiac twin at the level of the cord insertion site, and the vessels supplying the acardiac twin are ablated.

Because of the need for highly specialized training and equipment, procedures for in utero therapy for TRAP are not widely available. Further, outcome data are limited to short-term outcomes. Thus far, randomized clinical trials have not been published, making it difficult to preferentially choose one technique over another. However, given the data that are available, both laser therapy and radiofrequency ablation seem to be safe and effective procedures. In general, studies report a survival rate of 80% to 90% for the pump twin after definitive therapy. Radiofrequency ablation is associated with a 22% risk for preterm premature rupture of membranes. Intrafetal laser ablation is associated with a 40% risk for preterm delivery. Maternal complications are uncommon and include bleeding, need for laparotomy to complete the procedure, thermal injury, chorioamnionitis leading to maternal sepsis, and disseminated intravascular coagulation.

### **Monochorionic Twins Discordant for Anomaly**

The rate of fetal anomalies is higher among twin pregnancies than singletons. In a population-based study of more than 2,300 twin pregnancies and 147,000 singletons, the prevalence of congenital anomalies in MCDA twins was 633.6 per 10,000 compared with 343.7 per 10,000 for DCDA twins (RR 1.8). In particular,

the excess risk among MCDA twins was attributable to anomalies of the central nervous system and to chromosomal and musculoskeletal anomalies.

Selective termination of the anomalous fetus using an intracardiac injection of potassium chloride cannot be performed for MCDA pregnancies because of the vascular anastomoses and risk for embolization of toxic materials to the nonanomalous twin. One of the methods described earlier in this chapter may be used to occlude the cord of the anomalous twin, typically at the abdominal cord insertion site.

### Fetal Anemia

Rh sensitization has become increasingly rare since the advent of Rho(D) immune globulin (RhoGAM), but cases of Rh isoimmunization that require fetal intervention can still be found. Rh isoimmunization can develop when an Rh-negative mother is pregnant with an Rh-positive fetus. If the mother has been exposed to Rh-positive cells in the past, then she will have circulating antibodies to the Rh antigen. When re-exposed to the Rh antigen (eg, during a subsequent pregnancy with an Rh-positive fetus), these antibodies rapidly increase in number. These antibodies can cross the placenta and attack the fetal red blood cells, resulting in hemolysis and fetal anemia. In severe cases, the anemia may lead to heart failure and hydrops, and subsequent death. Most cases of Rh isoimmunization causing severe hemolytic disease of the fetus and newborn are the result of incompatibility with the D antigen. However, severe hemolytic disease of the newborn can occur with other red blood cell antigen incompatibility, such as Kell. The overall prevalence of Rh incompatibility varies based on race and ethnicity but is estimated to be 6.8 cases per 1,000 live births based on birth certificate data as reported by the US National Center for Health Statistics in 2003.

Currently, all pregnant women receiving prenatal care are tested for their Rh type at the beginning of pregnancy and treated with RhoGAM when necessary. Additional doses may be given for episodes of vaginal bleeding, after procedures such as chorionic villus sampling and amniocentesis, or after direct abdominal trauma when fetomaternal hemorrhage is suspected. For women who are known to have Rh antibodies and who are at risk for having an Rh-positive fetus, serial antibody titers are followed throughout the pregnancy. A critical maternal titer is the titer associated with a significantly increased risk for fetal anemia. Each laboratory will have an established critical titer, typically between 1:8 and 1:16. If the titer exceeds this critical number before 35 weeks' gestation, the fetus is monitored more closely for anemia. The gold standard for detection of fetal anemia using invasive methods is amniocentesis to check the optical density of the amniotic fluid based on the heme pigment produced by hemolysis. This value, known as the DOD<sub>450</sub> value, was originally plotted on a Liley curve that was divided into 3 zones and designed for use in pregnancies from 27 weeks' gestation to term. The Liley curve was then modified by Queenan in 1993. The Queenan curve consisted of 4 zones and included data for pregnancies as early as 14 weeks' gestation. In 2000, Mari and colleagues found Doppler measurement

of the MCA PSV of greater than 1.5 MoM to be a reliable screening tool for fetal anemia, with a low false-positive rate of only 12%. Subsequent studies have confirmed the reliability and sensitivity of MCA Doppler ultrasound. Compared with amniocentesis for DOD<sub>450</sub>, MCA PSV had a sensitivity of 88% versus 76%, specificity of 82% versus 77%, and accuracy of 85%. These data confirmed that MCA PSV can safely replace DOD<sub>450</sub> in the management of Rh isoimmunization. A meta-analysis in 2009 further confirmed that MCA PSV is the gold standard for noninvasive screening for fetal anemia.

In severe anemia, the current practice for treatment involves a fetal blood transfusion using percutaneous umbilical blood sampling (PUBS) or cordocentesis. PUBS is performed by introducing a needle into the fetal umbilical cord. A small amount of blood is withdrawn, and a Coulter counter determines the opening fetal hematocrit. Based on this initial value, a calculation is made to determine the amount of blood that should be transfused to the fetus. Irradiated, leukocyte-depleted, cytomegalovirus-negative, type O, RhD-negative red blood cells are transfused into the fetus for a target hematocrit of 40% to 50%. On average, the fetal hematocrit will decline approximately 1% per day from hemolysis related to Rh incompatibility. Given this, the procedure may need to be repeated several times during the pregnancy. The risks of PUBS include non-reassuring fetal status, spontaneous rupture of membranes, preterm labor, and intrauterine infection. It is important to note that in order to allow the fetal cardiovascular system to compensate for the acute change in volume and viscosity, the hematocrit should not be raised by more than fourfold in a single transfusion.

### ETHICAL CONSIDERATIONS IN FETAL INTERVENTIONS

Since the 1980s, the fields of prenatal diagnosis and fetal intervention have experienced dramatic advances. Because of the significant risks associated with open fetal surgery and earlier, more invasive procedures, fetal intervention was previously reserved for diseases that would otherwise be lethal without intervention. With improvements in ultrasonography and more widespread use of MRI, fetal abnormalities are being diagnosed at earlier gestational ages. In addition, with the increasing number of centers offering fetal intervention and the improvements in minimally invasive approaches to fetal intervention, the application of fetal intervention has expanded to include a wider number of diseases.

The American College of Obstetricians and Gynecologists (ACOG) released a Committee Opinion in 2011 regarding maternal-fetal intervention and fetal care centers. The statement emphasizes the overarching goal of fetal interventions, which is to improve outcomes for children by intervening before birth to correct or treat prenatally diagnosed abnormalities. Correcting a fetal malformation with open surgery, fetoscopy, or ultrasound-guided procedures can be risky to both fetus and mother, inadvertently increasing both maternal and perinatal morbidity and mortality

rates. The need to balance risks to the mother and fetus against potential benefits to the fetus forms the basis for the fundamental ethical conflict when considering fetal surgery. Additionally, the psychosocial risks to the mother and family of losing the pregnancy or, in the event of iatrogenic injury to the fetus, living with a child impaired with further damage must also be considered. Finally, residual risks to future pregnancies must also be taken into account. For these reasons, ACOG and the American Academy of Pediatrics recognize that these interventions always require the free informed consent of the pregnant woman, who always has the right of refusal.

Criteria have been set for considering fetal intervention, including that prenatal diagnosis techniques should identify the malformation and almost certainly exclude any abnormalities that will result in death; the defect should have a defined natural history and cause progressive injury to the fetus that is irreversible after delivery; repair of the defect should be feasible and should reverse or prevent the injury process; and the surgical risk must not entail excessive risk for the mother or her future fertility. Meeting these prerequisites is extremely important because most fetal malformations do not directly threaten the mother's health.

The investigational nature of these interventions, offered at a limited number of centers under research protocols, necessitates a rigorous, nondirective informed consent process that emphasizes the experimental basis for these interventions. Most of these procedures use a multidisciplinary approach including but not limited to perinatologists, neonatologists, radiologists, pediatric surgeons, pediatric subspecialty surgeons, anesthesiologists, and nurses. As therapies advance, public policy and insurance practices will likely continue to evolve. Centers performing fetal surgery have established *fetal oversight committees* that serve as a multidisciplinary advisory council, which ensures continuous monitoring of quality and function.

### Decision Making

Questions remain about both the safety and efficacy of many fetal surgical corrections. In some disorders, the natural history of the conditions is poorly understood, making outcome comparisons difficult when evaluating fetal therapy versus no treatment or postnatal intervention. In addition, when comparing fetal therapy with postnatal surgery, it is crucial to consider risks to the mother from exposure to anesthesia and surgery during the procedure, drugs used to prevent premature labor and delivery after the procedure, and the emotional burden of consenting to medical interventions with uncertain outcomes. This means that the benefits of these surgeries must be considered in the context of risks to both the pregnant woman and the fetus. Not every pregnant woman seeking fetal treatment is an appropriate intervention candidate. Consequently, the informed consent process should educate expectant parents so that their expectations about likely outcomes match current clinical realities. Precise information about the benefits of fetal approaches in the context of the natural history of the diseases or disabilities being treated, and disclosure of

information about the skill sets, experience, and success rates of medical teams performing each procedure should be provided. These measures would ensure that pregnant women (and their families) have the information necessary for shared decision making about fetal or neonatal interventions for life-threatening neonatal conditions. The pediatrician has an important role in collaboration with the maternal-fetal specialist and other pediatric subspecialists in supporting families through these difficult and delicate processes, balancing hope with the reality of the condition and offering clear, compassionate communication regarding expectations and anticipated outcomes.

A framework for understanding how some families will approach decision making under these circumstances can be extrapolated from studies of parents whose young child has a life-threatening congenital heart defect. Described as "parenting under pressure," the process involves 4 phases: realizing and adjusting to the inconceivable, growing increasingly attached, watching for and accommodating to the unexpected, and encountering new challenges. Families confronting a prenatal diagnosis of a potentially life-threatening condition affecting their fetus must quickly channel through these stages as they gather and process information needed to make decisions for their child. It is equally important to recognize cultural variations in values that inform parental choices regarding their desire for potential fetal or neonatal interventions following a prenatal diagnosis and, in some instances, even decisions regarding whether to undergo extensive fetal assessment to more fully inform the degree of fetal involvement or anticipated illness severity.

### THE FUTURE

In utero transplantation with hematopoietic stem cells can possibly treat fetuses with various congenital disorders. Additionally, the advent of gene therapy will likely transform the management of in utero disease. Today, many potentially lethal inherited conditions have to be treated after birth with bone marrow transplantation, which can be complicated by lack of donor stem cells, irreversible damage in the neonate, or rejection of the donor cells. The idea of transplantation in utero is based on the theory that the fetal immune system is immature and will be more likely to overcome these problems. This treatment is novel and unproven. In utero transplantation will be considered for hemoglobinopathies, immunodeficiency diseases, inborn errors of metabolism, mucopolysaccharidoses, and more. Currently, most fetal interventions are used in situations in which the fetus would die without the intervention, such as Rh isoimmunization or TTTs.

As technology advances and physicians become more proficient with these techniques, ethical considerations will arise. However, most of the available evidence is based on case reports, case series, or reviews. There have been few prospective studies evaluating the superiority of one method over another. Despite the paucity of evidence in the literature, minimally invasive fetal interventions are being offered at more centers and are practiced by more physicians. Interventions originally

reserved for fetal abnormalities that would result in fetal death if untreated are now being offered for a wide variety of non-life-threatening fetal abnormalities. Should these therapies be offered for still more abnormalities, such as polydactyly or cleft lip? Society must weigh the cost of treating these defects in utero against the complications that may occur. Finally, outcomes of interest to parents, such as the child's long-term neurodevelopmental status, quality of life, and future health, as well as maternal health outcomes, are unknown at this point.

Despite these gaps in knowledge, there is a building momentum and body of literature in the field of fetal intervention. Studies evaluating long-term follow-up of these patients and their children will be invaluable in determining the future of fetal intervention.

### Chapter 84

## MATERNAL DEPRESSION

Marian Earls, MD

Perinatal depression is a pertinent issue for the primary care physician (PCP) because of the significant associated risks to the health and well-being of the infant and family. This chapter specifically discusses postpartum depression for the PCP who is providing care for the child of a depressed mother. Postpartum depression adversely affects early brain development and leads to increased costs of medical care, inappropriate medical care, child abuse and neglect, discontinuation of breastfeeding, and family dysfunction. Pediatric practices, as medical homes, can establish a system to implement postpartum depression screening and to identify and use community resources for the treatment and referral of the depressed mother and support for the mother-child (dyad) relationship.

Up to 12% of all women may experience depression in a given year. Socioeconomic status is a compounding factor, and if a woman has low income, the prevalence of depression is doubled to 25%. Forty to 60% of mothers who have low income report depressive symptoms (but do not necessarily meet criteria for a depressive disorder). Specifically, depression occurs in 8.5% to 11% of women during pregnancy and in 6.5% to 12.9% of women during the postpartum period. Major depression, as a subset of those statistics, occurs in 3.1% to 4.9% and 1% to 6.8%, respectively. The peak for minor depression occurs at 2 to 3 months postpartum, and for major depression at 6 weeks postpartum.

The spectrum of postpartum depression encompasses “postpartum blues” to postpartum mood disorders (PPMDs), which include postpartum depression and postpartum psychosis. Fifty to 80% of all mothers experience postpartum blues after birth. These symptoms are transient (beginning a few days after birth and lasting up to 2 weeks), but they do not impair function. Symptoms include crying, depressed mood, irritability, anxiety, and confusion.

Postpartum depression is categorized as a minor/major depressive disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition. Postpartum psychosis is a relatively rare event. Only 1% to 3% of women experience postpartum psychosis after birth. Occurring in the first 4 weeks after birth, impairment is serious and may include paranoia, mood shifts, hallucinations/delusions, and suicidal/

homicidal thoughts. Postpartum psychosis requires immediate medical attention. If a woman experiences PPMD, she is likely to experience it again with subsequent pregnancies. However, PPMD can also affect mothers even without a previous history with earlier births.

A mother can be placed at risk for depression if the child has difficult temperament, was premature, or has a chronic health condition. If a mother has difficulty reading her baby's cues, bonding may be difficult and interaction impaired.

### EFFECT OF MATERNAL DEPRESSION

In the setting of maternal depression, the effects on the infant's environment can adversely affect early brain development. It is known that migration of neurons and formation and pruning of synapses are affected by both genetics and the environment. Further, physiologic responses to stress in the infant's environment affect the infant's social-emotional development. The activation of the physiologic stress response system results in increased levels of stress hormones. Persistent elevation of cortisol can disrupt the developing brain's architecture in the areas of the amygdala, hippocampus, and prefrontal cortex and therefore ultimately affect learning, memory, and behavioral and emotional adaptation. When an infant lives in an environment of neglect, there can be visible changes on magnetic resonance imaging in the frontal lobes. The infant therefore is at risk for impaired social interaction and delays in language and cognitive development.

Maternal depression compromises bonding. When the mother is emotionally disengaged, an environment is created in which the infant withdraws from daily activities and may avoid interaction. As early as 2 months of age, the infant looks at the depressed mother less and can demonstrate poor state regulation, less interaction with objects, and lower activity level. The infant is at risk for failure to thrive and attachment disorder of infancy (deprivation/maltreatment disorder of infancy).

#### The Infant

Early signs and symptoms in the infant include poor orientation skills and tracking, lower activity level, and negative temperament. The developing infant may appear sad, lethargic, and withdrawn. The infant may have little interest in exploration. There may be feeding or sleeping problems. The infant may cry a lot and have difficulty both with self-comforting and with being soothed. The infant is likely to exhibit no caregiver preference and to go to anyone. The infant may resist touch or be clingy.

#### The Mother

Maternal depression impairs parenting skills. The mother's perception of the child's behavior is less positive. Her interaction is less attuned to the infant's cues and may be more controlling. On the other hand she may have apathy toward the baby and indifference to caregiving. She is likely to have impaired attention and judgment for health and safety. Further, there is an adverse effect on breastfeeding. The

Agency for Healthcare Research and Quality evidence report "Breastfeeding and Maternal and Infant Health Outcomes in Developed Countries" reviewed 6 prospective cohort studies regarding postpartum depression and breastfeeding. It revealed an association between not breastfeeding, or early cessation of breastfeeding, and postpartum depression.

Early response is urgent. If the mother continues to experience depression and there is no intervention for the dyad, the child's developmental issues are likely to persist and be less responsive to intervention over time. As noted previously, infants are at risk for insecure attachment. Children with insecure attachment are more likely to have behavior problems and conduct disorder. Higher cortisol levels in preschoolers are linked with anxiety, social wariness, and withdrawal. Attachment disorders, behavior problems, and depression can occur in childhood and adolescence. When mothers experience depression, the children, as they age, often have poor self-control, poor peer relationships, school problems, aggression, special education needs, grade retention, and early school exit.

### ROLE OF THE PRIMARY CARE PHYSICIAN

Postpartum depression leads to adverse effects on infant brain development, cessation of breastfeeding, family dysfunction, inappropriate medical treatment of the infant, and increased costs of care. To have a positive effect on the health of the child and family, medical homes can be timely and proactive by implementing screening, supporting the mother-child relationship, and identifying and using community resources for referral and treatment. PCPs who care for children need to promote awareness of the need for screening in the obstetric and pediatric periodicity of care schedules, use evidence-based interventions focused on healthy attachment and parent-child relationships, and promote training for professionals who care for very young children.

There is much support for the primary care setting to incorporate screening and interventions. The American Academy of Pediatrics (AAP) policy statement "The Future of Pediatrics: Mental Health Competencies for Pediatric Primary Care" recognizes the unique advantage of the primary care physician for surveillance, screening, and working with families to improve mental health outcomes. The "primary care advantage" derives from the following characteristics:

- Longitudinal, trusting relationship with the family
- Family centeredness
- Unique opportunities for prevention and anticipatory guidance
- Understanding of common social-emotional and learning issues in the context of development
- Experience in coordinating with specialists in the care of children and youth with special health care needs
- Familiarity with chronic care principles and practice improvement

The AAP Task Force on Mental Health promotes the use of a common factors approach to engage families and build an alliance for addressing mental health

issues. Bright Futures health promotion themes include Family Support, Child Development, and Mental Health. Specifically, Bright Futures includes surveillance for parental social-emotional well-being as well. Psychosocial screening and surveillance for risk and protective factors is an integral part of routine care and the relationship with the child and family. Opportunities for prevention and promotion in primary care include the following:

- Prenatal visits (the prenatal visit is the first in the Bright Futures periodicity schedule)
- Psychosocial and maternal depression screening
- Developmental and behavioral screening and surveillance
- Social-emotional screening for children identified at risk

Implementation of these screening opportunities requires a quality improvement approach to office process.

## SCREENING FOR POSTPARTUM DEPRESSION

Based on the peak times for the occurrence of the spectrum of PPMD, the 1-, 2-, and 4-month well-child visits are appropriate times to screen for maternal depression. Screening tools are simple and include the Edinburgh Postpartum Depression Scale (EPDS) or the Patient Health Questionnaire-2 (PHQ-2), both of which are endorsed by the US Preventive Services Task Force. The EPDS has 10 multiple-choice questions and is completed by the mother. A score of 10 or greater indicates possible depression; a score of 20 or greater requires immediate referral for emergency mental health services. The screen is available in English and Spanish and can be accessed online. The PHQ-2 has only 2 questions and is not specific to the postpartum period; it can be used during pregnancy, for surveillance, and to indicate risk for depression in adults in general. The 2 questions are as follows:

- Over the past 2 weeks, have you ever felt down, depressed, or hopeless?
- Over the past 2 weeks, have you felt little interest or pleasure in doing things?

The prenatal visit is an excellent opportunity to discuss strengths and stressors during pregnancy, including depression. The PCP may be able to provide anticipatory guidance and initiate supportive strategies for the mother even before the baby's birth. Communication between the obstetrician and PCP is desirable for this reason.

To follow up on depression concerns and the effect on the mother-infant relationship, use of a screen for infant social-emotional development and interaction is appropriate. The Ages and Stages Questionnaire—Social-Emotional (ASQ-SE) is one such tool. It is completed by the mother and has a single cutoff score. It provides information about infant caregiver interaction and screens affect, self-regulation, adaptive functioning, autonomy, compliance, and communication. The 6-month tool is used for infants who are 3 to 8 months of age. Another infant social-emotional screening instrument that is available and in the public domain is the Baby Pediatric Symptom Checklist (BPSC), available at the Survey of Wellbeing of Young

Children Web site ([www.theswyc.org](http://www.theswyc.org)). It assesses irritability, inflexibility, and difficulty with routines and is to be used for children younger than 18 months.

## WHEN SCREENING SHOWS A CONCERN

When a depression screen is positive, management will vary according to the degree of concern and need. At the very least, it will require support and demystification. Management includes the following:

- Communication
- Demystification
- Support resources (family and community)
- Referrals to integrated/co-located mental health provider
  - For the mother
  - For the dyad
  - For the child (for targeted promotion and early intervention).

Demystification is directed at removing the mystery about maternal depression—emphasizing that postpartum depression happens with many women, that it is not the mother's fault and she is not a bad mother, that she will feel better and depression is treatable, and that the PCP is a resource and other help is available. Having a baby is a time of transition that can be difficult when there are other stressors but can be eased when there are other supports. A brief intervention at the visit could include the following:

- Promote the strength of the mother-infant relationship
- Encourage understanding and responding to the baby's cues
- Encourage routines for predictability and security
- Encourage focus on wellness: sleep, diet, exercise, stress relief
- Acknowledge personal experiences
- Promote realistic expectations and prioritizing important things
- Encourage social connections

Intervention for the mother may include support, therapy, medication, emergency mental health services, and hospitalization. Note that mild depression does not generally require medication. For these services, the mother can be referred to her own PCP, her obstetrician, or an adult mental health provider.

Immediate action is necessary if the EPDS score is 20 or greater, if the mother expresses concern about her or her baby's safety, or if the PCP suspects that the mother is suicidal, homicidal, severely depressed, manic, or psychotic. Referral to emergency mental health services (most communities have mental health crisis teams/services) is needed, and the mother should leave the office with a support person (not alone) and a safety plan.

Intervention for the dyad includes the following:

- Follow-up ASQ-SE, and, if attachment issues are indicated,
- Therapy with a child mental health professional regarding attachment and bonding,
- Referral to Part C, Early Intervention services.

The father may also have depression, and the incidence may be higher if the mother is depressed. A father who is not depressed may be a protective factor.

If the practice has an integrated mental health provider, such as a licensed clinical social worker or counselor, that provider can provide immediate triage for a positive screen, administer secondary screens, offer support and follow-up, facilitate referrals, and coordinate follow-up with the PCP.

Referrals for the mother could be to her own PCP, her obstetrician (who may be the mother's PCP or may have an integrated mental health professional linked with their practice), or an adult mental health professional for individual or couple therapy and, if needed, medication.

Referrals for the dyad should be to a professional who has expertise in the treatment of very young children. Evidence-based treatments include Circle of Security (COS, for children aged 0–5 years), Parent–Child Interactive Therapy (PCIT, for children aged 3–7 years), Child–Parent Psychotherapy (ABC, for children aged 0–5 years), and Attachment and Biobehavioral Catch-Up (ABC, for children aged 0–5 years). Part C services can provide modeling and support for interaction and play with the infant to promote healthy development.

Other community resources for the family include the following:

- Public health nurses
- Lactation specialists
- Parent educators
- Family support groups
- Parent–child groups
- Mother's morning out
- Early Head Start
- Mentoring and home visitation such as Parents as Teachers, Healthy Families America, and faith-based or other volunteers

## CODING AND BILLING

The AAP recognizes the EPDS or PHQ-2 as a measure of risk in the infant's environment; therefore, billing is appropriate at the infant's visit with the infant as the patient. The Current Procedural Terminology (CPT) code for this screen is 99420. The CPT code for the ASQ-SE may be 96110 or 99420, depending on the state. The Diagnostic Classification of Mental Health and Developmental Disorders in Infancy and Early Childhood: Revised Edition (DC 0-3R) coding for Deprivation/Maltreatment Disorder of Infancy is observed in the context of evidence of deprivation or maltreatment manifested by the following:

1. Persistent parental neglect or abuse of a physical or psychological nature, of sufficient intensity and duration to undermine the child's basic sense of security and attachment;
2. Frequent changes in, or inconsistent availability of, the primary caregiver, making an attachment to an individual caregiver impossible; or
3. Other environmental compromises and situations beyond the control of the parent and child that are

prolonged, interfere with the appropriate care of the child, and prevent stable attachments.

These statements describe the possible impact of significant or prolonged maternal depression on attachment.

## SUMMARY

Early brain development research highlights the importance of a healthy mother–infant relationship. Unrecognized and untreated, postpartum depression places this relationship and the infant at risk. The nonstigmatizing, longitudinal pediatric relationship lends itself to identifying maternal depression and supporting maternal and child health. Universal early, routine, structured psychosocial screening opens the door to broader communication with families and medical homes about mental health–related concerns. The PCP–family relationship provides the “primary care advantage” to facilitate healthy attachment and social-emotional development for the infant.

## MEDICAL-LEGAL CONSIDERATIONS IN THE CARE OF NEWBORNS

Jonathan M. Fanaroff, MD, JD; Robert Turbow, MD, JD

### INTRODUCTION AND OVERVIEW OF MEDICAL MALPRACTICE

About 4 million infants are born every year in the United States. Pediatricians, general physicians, and nurse practitioners provide most of the care to these newborns. Throughout this chapter, these physicians will be collectively referred to as *primary care physicians* (PCPs); however, the information presented here is intended for all physicians and other medical professionals who care for infants. Although most of these newborns will be healthy, the PCP will need to manage a variety of common but potentially harmful conditions, such as hyperbilirubinemia, hypoglycemia, and previously unrecognized congenital heart disease. Delays in the initiation of resuscitation and inadequate neonatal resuscitation are among the most common clinical situations leading to litigation against pediatricians and other physicians and nonphysician clinicians who care for newborns. Missed or delayed diagnosis and management of suspected sepsis or meningitis, perinatal injury, developmental dysplasia of the hip, and critical congenital heart disease may also give rise to substantial medical liability. Other issues in newborn care that pose liability for pediatric PCPs include missed newborn blood spot screening, missed hearing screening in the nursery, improper treatment of neonatal hypoglycemia, and delayed response to neonatal seizures or hyperbilirubinemia. Factors that contribute to potential liability encompass failure to perform appropriate screening evaluations or risk assessment, poor communication, incomplete documentation, failure to recognize and appropriately treat high-risk conditions that may contribute to a particular neonatal condition, and inadequate or delayed follow-up care.

Unfortunately, medical malpractice liability is in the midst of a new crisis. Indeed, the American Medical Association (AMA) estimates that 20 states are currently in a medical liability crisis, defined as a situation in which patients lose access to care as a result of the medical liability system. In 2010, both the Illinois and Georgia Supreme Courts struck down their medical malpractice caps as unconstitutional. Additionally, the AMA published a survey in 2010 showing that an average of 95 claims were filed for every 100 physicians.

Although liability problems have occurred in the past, the current effect on young physicians is severe. A 2008 survey of final-year residents found that 69% of residents were significantly concerned about malpractice, up from only 15% in the 2001 survey. Furthermore, many surveys have revealed physicians' increasing dissatisfaction with medical practice, in part because of liability concerns.

The specialty of pediatrics ranks fourth in highest average indemnity from 1985 to 2004, behind neurology, neurosurgery, and obstetrics and gynecology. Furthermore, the Physician Insurers Association of America (PIAA) reports that the average closed pediatric malpractice claim was \$316,521, compared with \$212,722 for all specialties. The high claim amounts result because many of the common diagnostic errors in newborns, such as meningitis, may lead to catastrophic and permanent injuries. Furthermore, the appearance of these permanently handicapped children in court or on video can generate enormous sympathy from juries. Finally, there are substantial costs of care when newborns are permanently injured. In a study conducted by Hickson and colleagues, families whose infants experienced permanent injury or death after a perinatal event were interviewed after the end of litigation regarding their reasons for filing malpractice claims. Important among the reasons cited by parents was a dissatisfaction with the physician-patient (family) communication: 13% did not believe their physician would listen to them, 32% believed that their physician did not speak openly, and 48% expressed feeling that they were intentionally misled. Seventy percent of participants stated that their physician did not inform them about the potential for long-term neurodevelopmental problems in their children. Families who believe that they are uninformed often assume that a complication that occurred is a result of a mistake and that the hospital staff is afraid to acknowledge this error. Issues of blame may be compounded further by parental concerns about their own responsibility for the infant's condition. Ultimately, the family may ascribe blame to the medical caregivers.

This chapter explores medical-legal issues that the PCP encounters in the delivery room, the newborn nursery, and the office. The chapter also addresses common malpractice risks that the PCP faces in dealing with sick newborns, as well as consultation, transport, and referral issues. The final sections of the chapter examine communication issues, patient safety, and ways to minimize liability risk. The goal is to assist practicing physicians in understanding their rights, duties, and liabilities as physicians (see also Chapter 11, Ethical Issues for the Primary Care Physician).

## MEDICAL-LEGAL CONSIDERATIONS IN THE DELIVERY ROOM

Prudent physicians who attend deliveries will be familiar with the various clinical challenges they may face in the labor and delivery area. The care provided in the delivery room has lifelong implications. Quickly recognizing and treating potential complications can help ensure an infant's smooth transition to extrauterine life. Although a PCP will generally not be held to the same standard of care as that of a neonatologist, merely taking call coverage for labor and delivery mandates that the pediatrician be knowledgeable and experienced in the management of common complications of parturition. An important facet of this preparation is maintaining training in the neonatal resuscitation program and understanding the potential pitfalls associated with resuscitating and stabilizing a newborn.

As in other areas of medicine, appropriate preparation, intervention, and documentation are essential. The pediatrician should be well informed concerning the capabilities of the birthing facility and the training of the personnel, given that approximately 10% of newborns require resuscitation after birth. Although most newborns who will require resuscitation can be anticipated based on maternal risks, pregnancy risks, or both, 1% to 3% of low-risk pregnancies will result in an infant who requires resuscitation at birth. If significant pregnancy complications or fetal abnormalities are noted before labor, then the newborn should be delivered at a facility that offers comprehensive care for the newborn. Primary care physicians should ask themselves a series of questions. Can this facility handle this delivery? Are the appropriate equipment and properly trained personnel available? What will be the course of action if the newborn has complications that cannot be addressed at the delivering facility? If circumstances permit, the pediatrician may consult with the woman's obstetric caregiver to convey the concerns for the soon-to-be-born infant. If time permits and the safety of the mother and fetus are not compromised, maternal transport to a facility offering a higher level of care may be possible. In cases in which this transfer is not practical, the pediatrician should consider notifying the neonatologist at the affiliated regional perinatal center for assistance and preparation for transport should the newborn require specialized or neonatal intensive care.

Primary care physicians should immediately familiarize themselves with the labor and delivery room area of any hospital they will be covering. Inadequate resuscitation may result from not anticipating the need for resuscitation, lack of appropriate and functioning equipment, presence of unskilled resuscitators, or errors in sequencing resuscitation steps. The last of these factors often includes delays in establishing an airway and initiating positive pressure ventilation, providing chest compressions, and administering the appropriate medications. If the newborn is being delivered through thick meconium and the head is crowning, this is not the appropriate time to discover that the laryngoscope is not functioning. During a delivery room resuscitation, the pediatrician is typically considered to be in charge of the newborn's care and any

resuscitative measures that may be needed. If the pediatrician is not present, then the obstetrician may be deemed responsible for the newborn's assessment and care. The obstetrician may delegate this responsibility to the anesthetist if one is present and if a pediatrician is not available. Much as the general surgeon may be held responsible for the negligent acts of an operating room nurse, the resuscitating pediatrician may be found to have some degree of liability for malfunctioning equipment or poorly trained staff. Because the supervising pediatrician is in a position to coordinate and direct the activities of others, this physician may have liability for persons who are assisting. Miscommunication and a perception of ineptness by close observers may further contribute to a family's decision to file a malpractice claim. The American Academy of Pediatrics (AAP) and American Heart Association Neonatal Resuscitation Program (NRP; [www.aap.org/nrp](http://www.aap.org/nrp)) is placing increasing emphasis on simulation and active measures to improve communication and teamwork.
